Hemodynamically Stable Patients. In patients who are hemodynamically stable, CT is the widely preferred diagnostic modality because of its ability to specify organ pathology, semiquantitate hemoperitoneum, and study nonabdominal body regions. Its potential drawbacks in certain clinical circumstances must be understood, however. US, DPL, and, very uncommonly, laparoscopy can be used in a complementary or primary mode.

Operative versus Nonoperative Management. Patients with certain intra-peritoneal injuries can be watched expectantly and need not be subjected to laparotomy. Specifically, this has been successful with even moderate- to high-grade liver or spleen trauma.
Failures, including deaths, have occurred with this approach, however. Thus, although it is preferable to avoid unnecessary laparotomy, it is imperative to prevent significant morbidity or mortality by waiting too long. The patient with normal sensorium and minor to intermediate severity of mechanism is a superior candidate for expectant management. It is critical that an institution appraise its ability to treat such patients. This includes having experienced nursing staff, trauma surgeons, and radiologists and the ability to take a patient to undergo laparotomy urgently if the need arises.

Several pitfalls in the expectant approach are noteworthy. First, multiple injuries of intraperitoneal organs, including hollow viscera, are common. Operative management of hollow visceral injury is necessary, and delay can have severe consequences. The ability of CT to detect coincident injury to these structures was discussed earlier. The patient with multisystem injury and, specifically, closed head trauma is most vulnerable to having delayed diagnosis of perforated intestinal injury. Second, expectant management may lead to increased use of blood products. Finally, this management approach fails in those patients whose hemorrhage is not amenable to therapeutic angiography and embolization and does not abate from apparent or misperceived minor injury of solid organs. In such cases, the lag time from injury to operation may increase morbidity and mortality.

Pelvic Fracture. In the setting of pelvic fracture, the clinical triage determinant is the presence or absence of hemoperitoneum (Fig. 43-13). Although the sensitivity of FAST US in patients with pelvic fractures is decreased, it still serves as a tool to triage the patient to the next intervention. In an unstable patient, a positive FAST US is followed by a supraumbilical peritoneal aspirate. If this reveals 10 mL or greater of blood, then the patient should expeditiously move to laparotomy. If instead urine or other fluid is aspirated, then the patient should undergo pelvic angiography prior to laparotomy. If the FAST US is negative, then the patient should proceed to angiography with the presumed diagnosis of a life-threatening retroperitoneal bleed. In stable patients, early mechanical pelvic stabilization is advised (see Chapter 52) and CT, followed by pelvic angiography and embolization, are undertaken as early as possible in the context of the multiple injuries.

Multiple System Injury. Treatment of the abdominal trauma patient with more than one life-threatening injury cannot be dogmatic. It is not unusual to confront intraperitoneal hemorrhage in a patient with apparent closed head injury or suspected blunt aortic disruption or both. Repair of the abdomen is said to take precedence over that of the head and chest. However, these situations are highly complex, and decision making is influenced by numerous and dynamic variables. The key tenet is that a patient with known hemoperitoneum whose vital signs cannot be stabilized must undergo laparotomy or face imminent exsanguination.

Closed Head Injury. In general, patients with coincident severe closed head injury but without frank coma or lateralizing signs do not have intracranial lesions that require craniotomy. When lateralizing features do exist, the clinician must choose between rapid prelaparotomy CT of the head or preemptive burr holes at laparotomy. This judgment rests mostly on the clinical state of the patient with particular regard to his or her response to resuscitative measures and the timely availability of CT. An approach to this scenario is presented in Figure 43-14.

Blunt Aortic Injury. Clinical or radiographic features that portend great vessel injury, notably a widened mediastinum on a supine anteroposterior chest radiograph, have variable sensitivity and specificity. In addition, although the course of any single aortic lesion is unpredictable, there is more likely than not a lag of at least several hours before rupture. Therefore, exigent laparotomy should precede great vessel diagnostics. Should the patient’s condition precipitously deteriorate, left lateral thoracotomy allows for aortic cross-clamping with its circulatory benefits and generally affords access to the injured portion of the vessel (Fig. 43-15).

FAST has been found to be useful for the detection of free fluid and can be used in triage to send the unstable child with visualized hemoperitoneum for laparotomy. However, the FAST appears to have less sensitivity in children than in the adult experience. Therefore, DPL, specifically peritoneal aspiration, can also uncover hemoperitoneum in the initial treatment of the critical, multiply injured child. Reliance on cell count alone has prompted significant nontherapeutic laparotomy rates.

In the course of expectant treatment, the child should undergo laparotomy if instability develops, transfusion requirements are excessive, peritoneal signs are unequivocal, or observation is not feasible because of associated injuries or lack of institutional resources. Closed head injury need not preclude nonoperative management of known solid parenchymal injury, but the risk associated with undiscovered and coincident hollow viscus perforation is greatly increased. The diagnostic approach to penetrating trauma in children is the same as that in adults.

Transfer. Trauma patients in rural settings may require a stabilizing damage control laparotomy by a general surgeon prior to being transferred to a trauma center for definitive care.
KEY CONCEPTS

- The accuracy of physical examination is limited in cases of blunt and penetrating trauma. It is rendered less reliable by distracting injury, altered sensorium (e.g., head trauma, alcohol or drug intoxication, mental retardation), and spinal cord injury.
- Implements and missiles frequently violate the lung parenchyma, diaphragm, mediastinum, intraperitoneal cavity, and retroperitoneum in some combination.
- The choice of diagnostic studies for abdominal trauma is based on clinical need first and foremost, as well as study availability and the accuracy of that study in a respective center.
- FAST US and peritoneal aspiration are rapid methods of determining or excluding the presence of hemoperitoneum in the critically ill blunt or penetrating trauma patient. DPL is more sensitive but invasive. FAST is noninvasive and is equally accurate, and it can simultaneously evaluate for hemopericardium and pneumothorax.
- Clinical indications for laparotomy are more dependable in and more frequently applicable to cases of penetrating trauma than cases of blunt trauma.
- The critical determinant in hemodynamically unstable patients with pelvic fracture is the existence of active intraperitoneal hemorrhage. Discovery of this by FAST US, CT, or peritoneal aspiration advises laparotomy, whereas its absence prompts diagnostic and potentially therapeutic angiography.

Despite considerable advances in the initial evaluation and management of severe injuries, confusion remains regarding the recognition and subsequent management of genitourinary trauma. Only major renovascular injuries or a severely shattered kidney, both of which are rare, portend a rapid death. Thus, most genitourinary injuries pale in comparison with the immediate life threats posed by concomitant injuries to the head, chest, and abdomen. Hence, the urinary tract as an anatomically injured system is by necessity relegated to a position of secondary importance. Nevertheless, to maintain excellence and expertise in the overall treatment of all injured patients, it is mandatory for the emergency physician to have a thorough understanding of the global spectrum of genitourinary injury and how it can affect patient outcomes.

Genitourinary trauma is frequently a covert entity and is associated with a wide array of injury. Approximately 10% of all multiply injured patients have some manifestation of genitourinary involvement. Because of its relatively infrequent occurrence and often subtle presentation, it may be overlooked in the initial evaluation of the multiply injured patient. Prompt identification and appropriate management of genitourinary injuries can minimize potential long-term complications, including renal insufficiency, chronic hypertension, incontinence, and sexual dysfunction. The astute emergency physician can accomplish this goal by a stepwise evaluation that considers the mechanism of injury, pertinent physical exam findings, urinalysis, and adjunctive diagnostic imaging.

For the stable patient, the urinary tract is unique in that diagnostic evaluation is always done in a retrograde fashion; that is, clinical suggestion and elimination of urethral injury before bladder injury before ureteral or renal injury. Adherence to this axiom enables the discovery of virtually any important urinary tract injury. Deviations from this practice may be necessary when life-threatening renal injuries are discovered.

Definitions

For purposes of investigation and staging of urologic injuries, genitourinary trauma is divided into lower tract (bladder or urethral injury), upper tract (renal or ureteral injury), and external genitalia (penile, scrotal, testicular, and vulvar injury). Each category is further subdivided on the basis of a blunt or penetrating mechanism of injury.

Historical Perspective

The basic tenets of lower urinary tract injury have not changed appreciably in the last 25 years. A thoroughly performed physical examination and the recognition of blood at the urethral meatus or gross hematuria identify all significant lower urinary tract injuries. Major advances in the identification of significant upper tract genitourinary injuries, their clinical markers, and ultimate staging procedures have come to the forefront over the last few decades. Before 1985, any trauma patient with any amount of microhematuria was labeled “at risk” for genitourinary injury and received an intravenous pyelogram (IVP). This was neither diagnostically definitive nor cost-effective and simply perpetuated the existing confusion and controversy. In 1985, Nicolaisen and colleagues published the first of a series of articles that established guidelines for identifying significant upper tract genitourinary injuries, their markers, and the diagnostic studies that define the exact extent of these injuries and aid in subsequent patient management.

In addition, the advent of ultrasonography has greatly simplified the diagnosis and management of external genitalia trauma.

Clinical Features

The signs, symptoms, and examination findings of genitourinary trauma are varied and nonspecific. Acutely, these may include flank, abdominal, rib, back, or scrotal pain; urinary retention; penile or scrotal ecchymosis or hematoma; blood at the urethral meatus; and an abnormally positioned prostate on digital rectal exam. Renovascular hypertension may be the only finding weeks to months after injury.

Physical Examination

Examination of the torso and pelvis during the secondary survey is the first step in the evaluation for urologic injury. Any evidence of abdominal tenderness should alert the examining physician to the possibility of a bladder rupture in addition to other intra-abdominal injuries. This likelihood increases significantly in the presence of a pelvic fracture. Tenderness elicited by pelvic compression or palpation of the pelvic girdle or pubic symphysis supports the diagnosis of a potential pelvic fracture with possible lower urinary tract injury.

Examination of the genitalia can be informative. The emergency physician should examine for evidence of hematoma or
Gross blood at the urethral meatus is suggestive of a urethral injury and dictates the need for retrograde urethrography. In circumstances in which emergency surgical exploration for life-threatening injuries is needed, the retrograde urethrogram can be performed in the operating room or after the operative procedure. In the male patient, classic teaching dictates that a Foley catheter should never be introduced when urethral injury is possible without first evaluating urethral integrity by retrograde urethrography. The concern is that trauma from the catheter placement may convert a partial urethral tear into a complete disruption. Although the literature on this topic is sorely lacking, one small retrospective review of 13 cases of urethral injury demonstrated no evidence that a blind attempt to insert a urinary catheter worsened the initial injury.

Careful inspection for blood at the vaginal introitus is particularly important in the female patient known to have a pelvic fracture. A vaginal examination can discern vaginal lacerations or urethral disruption caused by displaced bony pelvic fracture fragments. This examination should be conducted carefully so as to protect the hands of the examiner from injury as well as to prevent worsening of the injuries themselves. Unlike with male urethral injuries, urethrography is technically difficult and not routinely recommended in females thought to have urethral injuries because of the urethra's short length. The inability to pass a Foley catheter in a premenopausal female patient with a pelvic fracture signifies the potential for urethral injury and possible need for suprapubic urinary drainage. Successful passage of a Foley catheter in a patient with blood at the vaginal introitus does not exclude urethral injury, however, and these worrisome physical examination findings must be conveyed to the urologist, who can plan subsequent endoscopic or radiographic urethral evaluation accordingly. In an older postmenopausal female trauma patient, urethral injury must be distinguished from a superiority retracted urethral meatus and accompanying meatal stenosis. These preexisting conditions are common in an atrophic vaginal setting, and a 12- or 14-Fr coudé or Foley catheter usually is required to achieve successful bladder access.

The digital rectal examination evaluates sphincter tone, bowel wall integrity, the presence or absence of gross blood, and the position of the prostate. Normally, the posterior lobe of the prostate is palpable and well defined (Fig. 44-1). A pelvic fracture may disrupt the puboprostatic ligaments and the prostatomembranous urethra, resulting in significant retroperitoneal venous bleeding. This may produce a large pelvic hematoma that can displace the prostate superiorly, resulting in a boggy, ill-defined mass on rectal examination (Fig. 44-2). Although it has long been recommended as part of the routine evaluation of all trauma patients, multiple studies have questioned the utility of the rectal examination in this setting and have specifically demonstrated that a palpably abnormal prostate is an insensitive indicator of urethral injury. Thus the decision to evaluate for urethral injury should consider additional clinical features and not rely solely on the findings of the rectal examination.

**Foley Catheter**

In any trauma patient presenting with a major mechanism of injury and the absence of any findings suggestive of urethral injury, a Foley catheter should be passed into the bladder. The initial bladder effluent must be observed by the physician. Because of its importance in dictating subsequent patient evaluation, gross hematuria is conservatively defined as any color to the urine other than clear or yellow. The presence of gross hematuria indicates urologic injury. Rarely, severe rhabdomyolysis produces large quantities of urine myoglobin, the gross appearance of which can be confused with gross hematuria. In these cases, urinalysis documents the absence of red blood cells (RBCs) consistent with myoglobinuria. Most significant lower urinary tract injuries are accompanied by either the presence of a pelvic fracture with blood at the urethral meatus or gross hematuria on Foley catheter placement. Upper tract trauma, however, tends to be more subtle. It is often coincident with nonurologic organ disruption, the bleeding from which can be life-threatening. These events may dictate rapid volume resuscitation that can clear gross hematuria.
quickly. Moreover, blunt injury to the renovascular pedicle or penetrating ureteral injury may not produce gross or even microscopic hematuria.

A fracture of the pelvis with displacement of the symphysis may result in a laceration or avulsion of the prostatic urethra because of the shearing force on the fixed prostatic and membranous urethra. Injuries to the anterior and posterior urethra are caused by different mechanisms, involve different symptoms, and are treated differently.

Pathophysiology

Urethral disruption is the most significant injury that must be identified. Failure to do so may lead to significant morbidity. Urethral manipulation can convert a partial urethral tear into a complete tear, thus precluding accurate assessment of urinary output and subsequently potentiating the long-term complications of urethral trauma (e.g., urethral stricture formation and urinary incontinence). Anterior urethral injuries are most often caused by straddle injuries, falls, gunshot wounds, and self-instrumentation (Fig. 44-3).

Pelvic fractures account for most posterior urethral injuries (see Fig. 44-2). The risk of urethral injury varies with the specific type of pelvic fracture. High risk fractures include the straddle fracture, in which all four pubic rami are involved, and the Malgaigne fracture, which involves fracture and displacement of both ischiopubic rami anteriorly and the ipsilateral sacrum, sacroiliac joint, or ilium posteriorly. Urethral injuries are rarely associated with fractures that do not involve the ischiopubic rami. In a prospective, single-center study of 203 consecutive male patients with pelvic fractures, 51 sustained urethral injuries. Malgaigne and straddle fractures were significantly associated with urethral injuries, with odds ratios of 3.4 and 3.85, respectively. In the same series, the highest risk for urethral injury was seen in patients suffering a straddle fracture with concurrent sacroiliac diastasis (odds ratio 24). Among those sustaining fractures not involving the anterior pelvic arch, none had urinary tract injury..

Clinical Features

During the secondary survey, examination of the lower abdomen, pelvis, genitalia, and rectum provides both direct and indirect evidence to support or refute urethral injury. Urethral integrity is supported by lack of pelvic and suprapubic tenderness; absence of penile, scrotal, or perineal hematoma; lack of blood at the urethral meatus; and normal findings on digital rectal examination. These physical findings permit the
safe passage of a 14- or 16-Fr Foley catheter into the bladder if the patient is unable to void and provide a suitable specimen for evaluation.

Diagnostic Strategies

Catheter Placement

The following technique for catheter placement assumes a normal urethra and includes the use of sterile technique, proper control of the foreskin, the use of copious amounts of lubricating jelly, and the gentle passage of a 14- or 16-Fr Foley or coudé catheter into the bladder. In all uncircumcised patients, continuous foreskin retraction with a folded 4 × 4 inch gauze pad is necessary to control the foreskin during catheter placement (Fig. 44-4). Without this maneuver, the foreskin tends to repeatedly reduce itself over the glans penis, which contaminates the field and complicates the catheterization attempt. Slight resistance to the advancing catheter should be expected secondary to voluntary contraction of the external sphincter. This is more apt to occur in a combative, anxious trauma patient than in a cooperative or unconscious patient. When this occurs, the patient should be reassured and asked to relax the perineum and rectal area while gentle advancing pressure is applied to the catheter. This combined approach allows the catheter to navigate the external sphincter successfully and pass easily into the bladder. If reassurance and relaxation do not allow easy passage of the catheter in a male patient with clinical features suggestive of urethral injury, it should be removed and a retrograde urethrogram performed. In all cases, the catheter must be passed to its fullest extent before the balloon can be inflated safely, withdrawn to the point of catheter balloon approximation with the bladder neck, and left to drain. Inflation of the catheter balloon under any other circumstances may result in iatrogenic urethral trauma.

Successful passage of a Foley catheter precludes a complete urethral disruption. Nonetheless, the possibility of a partial urethral injury not manifested by history, mechanism of injury, or physical examination does exist. If this injury is suggested initially, a retrograde urethrogram should be obtained. The presence of urethral extravasation together with contrast material filling the bladder is diagnostic of a partial urethral injury (Fig. 44-5). Identification of a partial urethral injury enables one careful attempt at urethral placement of a 12- or 14-Fr Foley or coudé catheter, depending on the size of the patient. If any difficulty is encountered, the catheter should be removed and a urologist consulted. If a partial urethral tear is suggested subsequent to successful passage of a Foley catheter, a small feeding tube can be placed alongside the urethral catheter and a modified retrograde urethrogram performed. In this circumstance, the urethrogram is for documentation and subsequent management purposes only because appropriate therapy (Foley catheter drainage) has already been instituted.

Radiology

In male patients with possible urethral injury, a retrograde urethrogram is the diagnostic procedure of choice. Retrograde urethrography is not an emergency and should always follow more critical resuscitative measures.
In a patient with a pelvic fracture, the entire retrograde urethrogram should be conducted with the patient in a supine rather than oblique position. Certain authors recommend oblique films for portions of the retrograde urethrogram to enhance urethral definition. These views add little information to a good supine study. More important, pelvic fractures are often associated with significant venous bleeding and hematoma formation. Maintenance of this stable hematoma can be crucial in the initial hemodynamic resuscitation of the patient. Any patient movement from the supine to the oblique position has the potential to disrupt the organized hematoma and promote leakage of contrast material around the penis, which can simulate extravasation on the urethrogram and promote a spurious examination. Next, 60 mL (or 0.6 mL/kg in children) of full-strength or half-strength water-soluble contrast medium is injected slowly over 30 to 60 seconds. Overly forceful injection may result in intravasation of contrast material into the urethral venous plexus. A radiograph is taken during the injection of the last 10 mL of contrast material. Retrograde flow through the urethra and into the bladder without extravasation ensures continuity of the urethra and absence of urethral injury (Fig. 44-7). Extravasation of contrast material outside the urethra with concomitant evidence of bladder filling distinguishes a partial urethral injury (see Fig. 44-5) from a complete urethral disruption, in which contrast material will be absent from inside the bladder (Fig. 44-8). The latter situation requires urologic consultation for appropriate management, the timing and specifics of which remain controversial and depend on the location and mechanism of injury.6,11,12 In the interim, if measurement of urinary output is essential, the bladder should be accessed by the suprapubic placement of a peel-away sheath and Foley catheter using the Seldinger technique (Fig. 44-9). When venous intravasation of contrast is suggested, a postvoid film demonstrates clearing of any intravasated material while extravasated contrast from a urethral injury remains.

Management

If the clinical features of urethral injury are absent or the urethrogram is normal, the urethra is intact and a Foley catheter can be passed into the bladder. If a partial urethral disruption is identified, one careful attempt to pass a 12- or 14-Fr Foley
or coudé catheter can be undertaken. If this is unsuccessful or if a complete urethral tear of the urethra is detected, placement of a suprapubic catheter is often needed especially if the patient is in shock or requires osmotic therapy for a severe head injury.

The optimal definitive management of urethral injuries remains a subject of controversy in the urologic literature. Pertinent variables include the location of the injury (anterior vs. posterior), extent of the disruption (partial vs. complete), mechanism of injury, hemodynamic stability of the patient, and the presence of associated injuries. Treatment options vary from allowing a partial disruption to heal over a stenting urethral catheter to early or delayed, open or endoscopic repair. Adjunctive suprapubic urinary drainage is frequently indicated. Regardless of the specific management plan, the ultimate goals are the preservation of urinary continence and sexual function and avoiding the disruption of any pelvic hematoma.

In female patients, proximal urethral injuries are managed by immediate surgical exploration and repair as conservative management with proximal urinary diversion alone is associated with an increased risk of urethrovaginal fistulas or obliterator urethral strictures. Distal injuries may be managed by urethral catheterization. Regardless of the location of the urethral injury, associated vaginal lacerations require transvaginal repair to reduce the incidence of fistula formation.

**BLADDER TRAUMA**

**Anatomy**

When empty, the bladder lies almost entirely within the bony pelvis. It rests on the pubis and adjacent pelvic floor parts. When full, the bladder can extend up to the level of the umbilicus, where it is most vulnerable to blunt and penetrating trauma. The bladder consists of an inner longitudinal, a middle...
circular, and an outer longitudinal muscle layer. These three layers constitute the detrusor muscle, which contracts to propel urine out the urethra. Blood is supplied to the bladder by the internal iliac artery and vein. The nerve supply comes from the lumbar and sacral segments of the spinal cord. It includes parasympathetic motor fibers to the detrusor muscle and sensory fibers to the detrusor that give rise to the sensation of fullness and urgency when the detrusor is stretched. Sympathetic fibers innervate the blood vessels of the bladder and the bladder neck musculature.

**Pathophysiology**

Greater than two thirds of bladder injuries result from blunt trauma. Approximately 90% result from motor vehicle collisions as a result of trauma sustained due to ejection from the vehicle or the compressive force of the seat belt on a distended bladder. Approximately 80% of blunt bladder injuries are associated with fractures of the bony pelvis. Additional life-threatening, nonurologic injuries are common and confer a significant mortality risk. Penetrating injuries may be inflicted by gunshot wounds, stab wounds, or impalement injuries. The diagnostic evaluation of the bladder, like the urethra, can be accomplished quickly without elaborate radiographic equipment or can be part of the computed tomographic (CT) evaluation performed for the evaluation of nonurologic injuries.

Bladder injuries are classified as contusions, intraperitoneal ruptures, extraperitoneal ruptures, or a combination of intraperitoneal and extraperitoneal ruptures. Proper classification is important because treatment options differ with injury type. Intraperitoneal bladder rupture results from blunt lower abdominal trauma in a patient with a distended bladder. These blunt forces are directed to the dome of the bladder where the urachus originates during embryonic life. Because of this developmental hiatus, the dome is attenuated and represents the anatomic area most susceptible to rupture from the sudden rise in intravesical pressure associated with blunt trauma. The dome also is unique in its isolated peritoneal reflection so that rupture in this area most likely results in intraperitoneal urinary contamination.

Extraperitoneal rupture occurs almost exclusively with pelvic fractures when the associated shearing forces result in tearing of the anterolateral bladder wall at its fascial attachments. Occasionally, extraperitoneal rupture results from bladder laceration by a bone spicule from the fractured pelvis. Extravasated urine may be confined to the perivesical space or may dissect along tissue planes and extend to the penis, scrotum, thigh, anterior abdominal wall, obturator foramen, or retroperitoneum.

**Clinical Features**

Lower abdominal or suprapubic pain, the inability to urinate, or the presence of blood at the urethral meatus may alert the physician to the possibility of lower urinary tract trauma.

**Diagnostic Strategies**

**Laboratory**

Gross hematuria is the cardinal sign of bladder injury and is present in greater than 95% of cases. In the setting of pelvic fracture, gross hematuria indicates the need to investigate for bladder injury. Relative indications for bladder imaging include gross hematuria without pelvic fracture and microhematuria in the setting of pelvic fracture. Grossly clear urine in a blunt trauma patient without a pelvic fracture virtually eliminates the possibility of bladder rupture.

**Radiology**

Conventional retrograde cystography and retrograde CT cystography are the diagnostic procedures of choice for suggested bladder injury. It is key that these studies not be done in an antegrade fashion, as such studies (e.g., injecting intravenous [IV] contrast material, clamping the Foley catheter, and allowing the examination to depend on antegrade filling of the bladder from renal excretion of progressively dilute contrast material) may produce incomplete and spurious findings due to inadequate distention of the bladder.

**Conventional Retrograde Cystogram.** Performance of either conventional plain film retrograde cystography or CT retrograde cystography assumes or follows exclusion of urethral trauma and the presence of an indwelling Foley catheter in the bladder. A Toomey syringe alone without its central piston is used for gravity instillation of contrast material. Allowing the contrast material to freely infuse from a hanging bottle connected to an indwelling Foley catheter runs the risk of the tubing becoming disconnected, with contrast material subsequently leaking onto the examination table. This promotes an inaccurate examination that may result in an unnecessary operative procedure. In the setting of pelvic fracture, it is imperative that the patient remain supine throughout the examination rather than be repositioned obliquely for selected radiographs. This lessens the potential for rebleeding from an organized retroperitoneal hematoma.

A preliminary KUB or scout film is obtained to provide a baseline evaluation of the pelvic, abdomen, and surrounding bony structures. It will become the film of reference for the postevacuation radiograph obtained after completion of the cystogram. Potential areas of extravasation on the postevacuation film will be confirmed when compared with the preliminary KUB film. Contrast material should not be instilled into the bladder until the quality and anatomic information on the preliminary KUB film are confirmed.

Full-strength water-soluble contrast medium is instilled under gravity filling to one of three endpoints: (1) 100 mL with immediate fluoroscopic evidence of gross extravasation; (2) a total instillation of 300 to 400 mL in any patient 11 years of age or older; in patients younger than 11 years, the correct amount of contrast medium is determined by the formula

![Figure 44-10. Retrograde cystogram. A Toomey syringe without its central piston is connected to the catheter and held by the examiner while gravity-instilled contrast material fills the bladder.](image-url)}
Figure 44-11. Spurious retrograde cystogram. This examination resulted when the tubing from the contrast bottle became disconnected from the Foley catheter after both were placed on the examination table, and bladder filling was completed without direct supervision. **A**, Kidney, bladder, ureter (KUB) film. **B**, Postinfusion KUB film interpreted as intraperitoneal bladder perforation. **C**, Intraoperative retrograde cystogram showing no evidence of extravasation.
Figure 44-12. Retrograde cystogram.

(age in years + 2) × 30; or (3) the instillation of a lesser amount than 100 mL, which initiates a bladder contraction. This becomes evident by the retrograde filling of the Toomey syringe with bladder contents. After a few minutes, the original contrast material can again be instilled to the point of stimulating a bladder contraction, at which time an additional 50 mL of full-strength contrast material should be injected slowly but forcefully into the bladder. The Foley catheter is clamped, and an anteroposterior radiograph is taken of the filled bladder (Fig. 44-13A and B). A lateral film may help clarify any areas in
Figure 44-13. Retrograde cystogram. A, Preliminary kidney, bladder, ureter (KUB) film. B, Film of filled bladder showing extravasation that could be intraperitoneal, as well as extraperitoneal. C, Film of patient in a lateral position shows no evidence of intraperitoneal extravasation.
question (Fig. 44-13C). After the film of the filled bladder meets standards for quality and detail, the bladder should be completely evacuated into a large basin or, preferably, into an available bedside drainage bag. Any spillage of contrast material onto the pelvic genitalia or examination table may lead to false-positive findings on the postevacuation radiograph. The postevacuation film may disclose evidence of posterior bladder wall or extraperitoneal extravasation not seen on the anteroposterior radiograph of the filled bladder (Figs. 44-12 and 44-14).

In cases of extraperitoneal bladder perforation, contrast material is evident in the area of the pubic symphysis and pelvic outlet (Fig. 44-15). With intraperitoneal perforation, contrast material outlines intraperitoneal structures (e.g., loops of bowel, the liver, and spleen) (Fig. 44-16).

Several studies have documented that false-negative results are associated with the use of less than 300 to 400 mL of an age-appropriate amount of contrast material for cystography.\(^\text{15}\) This has been seen primarily in penetrating bladder injuries in which the perforation from a small-caliber gunshot wound or a thin blade stab wound can be missed. The anatomically interlacing bladder wall muscle fibers are arranged such that these wounds lend themselves to immediate muscle fiber reapproximation and tenuous sealing of the wound by covering peritoneum and intra-abdominal mesentery. Unless an adequate amount of full-strength contrast material is used to fully distend or even overdistend the bladder, extravasation will not be evident, the injury will be missed, and there will be potential for significant morbidity.

**Computed Tomography Retrograde Cystogram.** The same anatomic information regarding bladder injury may be obtained using retrograde CT cystography rather than routine plain film radiography.\(^\text{19-21}\) CT cystography is best obtained in trauma
patients who are undergoing CT evaluation for other possible injuries.

In either study, undiluted water-soluble contrast medium must first be instilled in a retrograde fashion. Intraperitoneal perforation is disclosed on helical CT scan by the presence of extravasated contrast material throughout the abdominal cavity (i.e., contrast ascites). Extraperitoneal extravasation is more difficult to visualize but can be appreciated on images taken through the pelvic area (Fig. 44-17A and B).

Management

In cases of bladder contusions, there is no evidence of extravasation on retrograde cystography. For these injuries, expectant management with or without Foley catheter drainage is the standard of care. Most uncomplicated extraperitoneal bladder ruptures heal spontaneously with urinary catheter drainage alone. Indications for operative repair of extraperitoneal ruptures include the presence of concomitant injury to the rectum or vagina, injury involving the bladder neck, or when laparotomy is required for other injuries. Intraperitoneal bladder rupture requires surgical repair. Without operative intervention, lower urinary tract contamination will infect initially sterile urine and promote the development of subsequent bacterial peritonitis. Bladder repairs are never emergencies and normally follow operative repair of life-threatening injuries.

UPPER TRACT

Renal Trauma

Perspective

Renal trauma rarely occurs in isolation. Concomitant nonurologic injuries may result in hemodynamic instability, necessitating prompt intervention and relegating the search for renal injury to a position of secondary importance. Significant renal injuries define a small subset of the trauma population at large, and mortality from renal trauma accounts for less than 0.1% of trauma deaths. This fact may lead to complacency and causes some of these injuries to be overlooked initially. Renal injuries are graded 1 through 5 according to the American Association for the Surgery of Trauma Organ Injury Scaling Committee Guidelines, which identifies most injuries requiring operative intervention.

Complications

Urinary extravasation is the most common complication of renal trauma, occurring in 10 to 30% of penetrating trauma and 2 to 18% of blunt injuries. There is considerable controversy in the urologic literature regarding the incidence of hypertension after renal trauma with reported rates varying greatly from as little as 0.2% to as much as 55%. Many experts currently believe the overall risk of hypertension after most renal injuries to be quite low. Factors affecting the risk of hypertension following renal trauma include the specific injury type and severity, with renal artery occlusion, although rare, imparting a risk of up to 50%.

Anatomy and Physiology

The kidneys are located in the retroperitoneal space, are surrounded by adipose tissue and loose areolar connective tissue, and lie along the lower two thoracic vertebrae and the first four lumbar vertebrae (Fig. 44-18). The kidneys are not fixed. They move with the diaphragm and are supported by their renal arteries, veins, and adipose tissue, which is connected to a layer of fibrous tissue called the renal fascia, or Gerota’s fascia.
The indented medial border of the kidney is called the **hilum**. The major renal vessels and ureter make up the renal pedicle and enter and exit at the hilum. The longitudinal section of the kidney (Fig. 44-19) shows an outer renal cortex and an inner renal medulla with its columns of Bertin. Each column of Bertin forms a papilla that empties into the renal pelvis. The renal pelvis is a funnel-shaped sac with cup-shaped extensions called **calyces**, which receive urine from each papilla and are the important decompression areas for rises in intrapelvic pressure.

The kidneys are perfused by 1200 mL of blood per minute, or 20 to 25% of cardiac output. Of this, 90% goes to the cortex and 10% to the medulla. Reduced blood flow to the kidney, whether from blunt or penetrating injury, causes renin to be released from the juxtaglomerular cells. Renin enters the bloodstream and combines with a plasma protein to form angiotensin. Angiotensin raises blood pressure by causing arteriolar vasoconstriction and acting on the adrenal cortex to augment aldosterone secretion. Aldosterone acts on the renal tubules to promote sodium reabsorption. Water follows passively with subsequent increase in blood volume. These changes increase blood flow to the kidney and other organs. The body requires only one third of normal renal function to sustain life. It is unusual in cases of genitourinary trauma to lose total renal function unless the patient has only one kidney, which carries a 1 in 1000 to 1 in 5000 incidence.

**Epidemiology**

Renal injury occurs in 1 to 5% of hospitalized trauma patients and represents the most common of all genitourinary injuries. Associated organ injuries occur in 61 to 100% of penetrating trauma and 35 to 55% of blunt injuries. Blunt trauma accounts for approximately 90% of injuries and occurs most often after motor vehicle collisions, falls from heights, or direct blows to the flank. The pathophysiologic mechanisms include rapid deceleration, displacement, and, rarely, an explosion-type injury of the ureteropelvic junction. Penetrating injuries tend to be more severe and are associated with a higher nephrectomy rate.

Renal vein injuries are more common than renal artery avulsions or intimal tears. Both injuries are often associated with rapid deceleration events. Most venous injuries tend to be partial rather than complete tears. As expected, a venous injury can potentially contribute more to a patient’s unstable hemodynamic status than an arterial injury as the protective secondary vasospasm that occurs following arterial transection does not occur with venous injuries. IV contrast-enhanced helical CT identifies most renal artery disruptions, whereas renal vein injuries must be indirectly diagnosed by the presence of a normal-appearing kidney in association with a large hematoma disproportionate to the rest of the radiographic study.
Diagnostic Strategies

Laboratory

Hematuria. The presence, absence, or degree of hematuria correlates poorly with the severity of renal injury. This is especially true in the setting of penetrating trauma. In select cases of blunt trauma, the distinction between gross and microscopic hematuria can be used to guide clinical decision-making when considered along with the patient’s hemodynamic status and the mechanism and severity of injury.27,29,30 Formerly, a trauma patient who exhibited gross or microscopic hematuria was labeled “at risk” for urologic injury and underwent IVP. Experience has shown that most of the identifiable injuries were renal contusions that could be managed expectantly. Moreover, in a significant number of severely traumatized patients, vigorous initial fluid resuscitation precluded satisfactory contrast concentration in the kidney, yielding an incomplete, nondiagnostic initial radiographic examination.

In 1989, Mee and associates published the hallmark article that established guidelines for the evaluation and treatment of renal trauma. Their 10-year prospective study of 1146 consecutive patients with blunt (88%) and penetrating renal trauma established that clinically significant blunt renal injuries are associated with gross hematuria, microscopic hematuria with shock (any systolic blood pressure less than 90 mm Hg), or, rarely but importantly, a history of sudden deceleration injury without hematuria or shock. In the same series, there was no correlation between the presence or absence of hematuria and the extent of renal injury among 139 cases of penetrating trauma.30

Pediatrics. In children, the kidney is the most commonly injured genitourinary organ.31 Controversy exists in the urologic literature as to whether the adult criteria for renal imaging following blunt trauma can be safely applied to the pediatric population.27,32,33 Owing to significant differences in physiology, hypotension is a late and unreliable indicator of shock in children.12,27 Additionally, unlike in adults, major blunt renal injuries can occur in the presence of microhematuria. The literature has defined 50 RBCs/hpf as the threshold below which imaging could be confidently dispensed with without missing significant injuries in children.31,34 Current guidelines support imaging for pediatric (16 years old or younger) patients with blunt renal trauma in the presence of gross hematuria, with microhematuria greater than 50 RBCs/hpf, or with significant deceleration injuries.27,35 As with adults, IV contrast-enhanced helical CT scanning is the diagnostic imaging technique of choice.

Radiology

Computed Tomography. IV contrast-enhanced helical CT is the diagnostic radiographic procedure of choice in evaluating significant upper tract renal trauma.12,27,29,36 CT detects renal contusions, lacerations, renal pedicle injuries, devitalized segments, and urinary extravasation (Fig. 44-20A-E). It allows for grading of renal injuries and provides important information about concomitant nonurologic injuries to abdominal and pelvic structures. Additional images obtained 10 minutes after contrast injection enable the detection of delayed extravasation and increases diagnostic accuracy.

Angiography. Angiography may be a useful adjunct to CT imaging in the stable trauma patient with suggested renovascular injury, such as renal artery thrombosis, laceration, or pseudoaneurysm, and may be therapeutic in cases where stenting or embolization are indicated.29,29,36

Intravenous Pyelography. Formerly, IVP was the most common imaging modality employed in the evaluation of renal trauma. It has been shown to be less accurate than CT, is time-consuming and labor-intensive, and images only the urinary tract.29 Despite these significant limitations, it may play a limited role in the initial evaluation of suggested renal trauma when CT is not readily available. In patients requiring immediate surgical intervention for other indications, a “one-shot IVP” performed in the emergency department or, more commonly, on the operating table may provide limited information to help the surgeon to stage upper tract injuries and confirm bilateral renal function. This test is performed by obtaining a single KUB film 10 minutes after the injection of 2 mL/kg of IV contrast (maximum 150 mL).28

Ultrasound. Ultrasound is not sufficiently sensitive to rule out possible renal trauma as it has been shown to miss up to 78% of known renal injuries.29,36 In the multiply injured trauma patient, ultrasound is useful in the evaluation for free fluid in the abdomen and pelvis, which may herald other significant nonrenal injuries; however, this modality cannot reliably distinguish blood from other types of fluid such as ascites or extravasated urine. Moreover, free intraperitoneal fluid may be absent in up to 65% of isolated renal injuries.19,36

Management

Blunt Injury

In the absence of a significant deceleration mechanism, adult blunt trauma patients without gross hematuria or shock (any systolic blood pressure < 90 mm Hg) and pediatric blunt trauma patients with microhematuria of 50 RBCs/hpf or fewer can be confidently discharged from the emergency department if hospital admission is not otherwise indicated. Outpatient urology follow-up until microhematuria has cleared is advisable to be certain it does not represent another more serious underlying condition.

The optimal management of blunt renal trauma depends on the type and severity of injury (Figs. 44-21 and 44-22), the patient’s hemodynamic status, and the management plan for any associated nonurologic injuries. The American Association for the Surgery of Trauma Organ Injury Severity Scale for the Kidney stratifies injuries and has been shown to correlate with the need for surgical intervention and the rate of nephrectomy.24 Grade I injuries include simple contusions and subcapsular, nonexpanding hematomas without parenchymal laceration. Grade II injuries are parenchymal lacerations less than 0.1 cm in depth without urinary extravasation and a stable, nonexpanding hematoma. Grade III injuries are parenchymal lacerations greater than 0.1 cm in depth without urinary extravasation. Grade IV injuries involve lacerations extending through the cortex, medulla, and collecting system or main renal artery or vein injuries with contained hemorrhage. Grade V injuries involve completely shattered kidneys or avulsion of the renal hilum and devascularization of the kidney.24 In one large retrospective review of 2467 patients with renal injury, the need for surgery increased from 0% of grade I injuries to 93% of grade V injuries. Likewise, the nephrectomy rate increased from 0% of grade I and II injuries to 86% of grade V injuries. Given that 80 to 90% are grade I or II, most blunt renal injuries can be managed nonoperatively with bedrest until any gross hematuria clears and periodic follow-up imaging to assess for injury resolution and to document renal function.

Immediate operative intervention is indicated for persistent life-threatening hemorrhage of possible renal origin. Restoration of normal renal function is unlikely after main renal artery injury, and nephrectomy may be required, especially in the presence of greater than 2 to 3 hours of complete or 6 hours of partial renal ischemia.27,37 In select patients, arteriography
with hemorrhage control by embolization is a reasonable alternative to laparotomy. When laparotomy is required for other injuries prior to adequate radiographic evaluation, blunt renal trauma may be surgically staged. In this setting renal exploration is indicated in the presence of an expanding, pulsatile, or uncontained retroperitoneal hematoma that is thought to indicate renal pedicle avulsion or when the injured kidney is not visualized on the one-shot IVP.

Penetrating Injury

In cases of penetrating renal trauma, the presence or absence of hematuria is of no consequence in predicting upper urinary tract injury. The location of the penetrating injury in relation to the urinary tract is the most important determining factor in deciding the need for radiographic investigation. Therefore, the absence of hematuria in a patient with a gunshot or stab wound in proximity to the urinary tract does not eliminate the need for IV contrast-enhanced CT as the initial diagnostic examination. Additional images obtained at 10 minutes after contrast injection are indicated to evaluate for delayed contrast extravasation and maximize the sensitivity of the study. Significant injuries to the kidney and ureter may occur in penetrating trauma without hematuria.

The majority of penetrating renal injuries require surgical intervention.

Figure 44-20. A, Renal artery injury. The right kidney demonstrates almost complete acute devascularization. (Note the right flank hematoma.) B, Subcapsular hematoma. Deforming renal parenchyma on the left. C and D, Renal laceration. These two images are of the same patient separated by several minutes of delay. The wedge-shaped hypodensities in the left kidney on the first scan (C) indicate the lacerations. The delayed scan (D) shows extravasation of contrast material from the lacerated kidney. E, Collecting system injury. Extravasation of contrast material from the lacerated left renal pelvis. (Hypodense areas of the kidney represent contusion.) URETERAL TRAUMA

Pathophysiology

Approximately 80% of ureteral injuries are iatrogenic, resulting from complications of abdominal or pelvic surgery, with the remainder due to external trauma. The ureters are relatively protected from injury by the bony pelvis, vertebral column, and psoas muscle. Thus, ureteral trauma is rare, representing only 1% of all genitourinary injuries. Gunshot wounds are the most frequently reported mechanism, with ureteral injuries complicating 2 to 3% of abdominal gunshot wounds.38,39

Blunt force trauma causes ureteral injury when a significant decelerating force results in avulsion of the ureter from its fixed points at the ureteropelvic junction or, less commonly, the ureterovesical junction. Due to the significant force required for ureteral injury, concomitant major organ injury occurs in approximately 90% of cases, and hypotension is present in greater than 50%.40

Clinical Features

There are no reliable signs and symptoms of ureteral injury in the acutely injured patient. Hematuria (gross or microscopic) is frequently present but may be absent in greater than 25% of patients, and thus its absence alone cannot be relied on to exclude the diagnosis.40 After blunt trauma, ureteral injury should be considered in patients with a significant decelerating mechanism, gross hematuria, or microscopic hematuria with hypotension. With penetrating mechanisms, ureteral injury should be considered when the injuring force occurs in proximity to the anatomic course of the ureter. Missed ureteral injury may manifest in a delayed fashion with a variety of signs and symptoms, including fever, nausea and vomiting, hematuria, flank pain, and a palpable flank mass.

Diagnostic Strategies

IV contrast-enhanced CT of the abdomen and pelvis is highly sensitive for visualization of upper tract injuries and is often indicated for the investigation of associated nonurologic injuries. Additional images obtained 10 minutes after contrast injection enable the detection of delayed extravasation and increase diagnostic accuracy.39

Retrograde pyelography (Fig. 44-23) is slightly more sensitive than IV contrast-enhanced CT for the evaluation of ureteral injury, but its performance is frequently impractical in the multiply injured patient and it is rarely undertaken in lieu of CT. Likewise, a formal IVP, although sensitive, is of limited utility due to the significant time required for study completion.40 In patients requiring immediate surgical intervention for other indications, a “one-shot IVP” performed in the emergency department or, more commonly, on the operating table may provide limited information to help the surgeon to stage upper tract injuries and confirm bilateral renal function. This test is performed by obtaining a single KUB film 10 minutes after the injection of 2 mL/kg of IV contrast (maximum 150 mL). The presence or absence of ureteral injury is subsequently confirmed during operative exploration.

Management

Operative repair is indicated for all ureteral injuries. With early diagnosis and appropriate treatment, the kidney and ureter can be saved in most cases. The complications of missed ureteral injuries are significant and include extended hospital stays, persistent urinoma, sepsis, loss of renal function, and death.41,42

EXTERNAL GENITALIA

PENILE TRAUMA

Anatomy

The penis contains three masses of erectile tissue (Fig. 44-24). The two corpora cavernosa constitute the main bulk and lie in the center of the penis. The smaller corpus spongiosum lies on the ventral surface of the penis, encaoses the urethra, and expands at the penile tip to form the glans penis. Blood is supplied by arteries lying in each of the three erectile masses and by the two dorsal penile arteries. A single dorsal vein drains most of the penis. The tunica albuginea is a dense fibrous envelope that surrounds the corpus spongiosum and each corpus cavernosum. Buck’s fascia overlies the tunica albuginea enclosing all three of the erectile masses, the dorsal arteries, dorsal nerve, and deep dorsal vein within a common compartment.

Clinical Features

Important historical factors to ascertain include the mechanism of injury and the state of the penis, flaccid or erect, at the time the injuring force was inflicted, as well as tetanus
immunization status. Penile injuries range from small lacerations or contusions to skin degloving or amputation. Strangulation injuries of the penile shaft inflicted by an encircling piece of string or hair may be seen in children (Fig. 44-25). Adolescents and adults may present with various objects of penile incarceration such as bottles, washers, and metal rings (Fig. 44-26). These objects are often used to facilitate masturbation, prevent detumescence, and heighten sexual pleasure. Prolonged application of these devices may result in loss of superficial skin, deep urethral necrosis, or eventual need for penile amputation.

The pendulous nature of the flaccid penis provides a measure of protection from blunt injury. By contrast, forceful bending of the erect penis may result in traumatic rupture of the corpora cavernosa, or penile fracture, due to tearing of the tunica albuginea. This injury may occur during vigorous sexual intercourse or masturbation. The patient often reports hearing a snapping sound followed by immediate pain, detumescence, and a slowly progressive penile hematoma (Fig. 44-27). In the majority of cases, the swelling and ecchymosis are localized to the penile shaft and contained by Buck’s fascia. The resultant appearance has been described as an “eggplant deformity.” If Buck’s fascia is torn, blood may track along fascial planes to the scrotum, perineum, and pubis. The corporal defect may be palpable on physical examination. Urethral injury occurs in 10 to 38% of penile fractures. The diagnosis is suggested by the presence of gross hematuria, blood at the urethral meatus, or the inability to void, but may occur even in the absence of these clinical findings. Urethral injury is present in up to 50% of all penetrating penile injuries.

Penetrating trauma to the external genitalia may be inflicted by stab wounds or gunshot wounds. These injuries are frequently associated with concomitant injuries to the bladder, urethra, rectum, testis, and the iliac and femoral vasculature. Penile amputation may result from interpersonal violence or as a manifestation of severe psychiatric disease.

The testicles are vulnerable to injury due to their location, but are relatively protected by the mobility of the scrotum, the tough tunica albuginea that surrounds the testes, and the cremasteric reflex. Eighty-five percent of testicular injuries are inflicted by blunt trauma, most commonly during sporting endeavors. Mechanisms include falls, kicks, and direct strikes by thrown objects. Testicular rupture occurs in greater than 40% of blunt scrotal trauma in patients who present to the hospital. Additional injuries include scrotal hematoma, hematocele, intratesticular hematoma, traumatic testicular torsion, testicular avulsion, testicular displacement, and epididymal injury. Symptoms include severe pain, faintness, nausea, vomiting, and occasionally urinary retention secondary to pain. Physical examination is often inadequate due to significant pain and swelling.
Figure 44-26. A, Self-induced priapism. This patient placed two steel washers (B) around the base of his penis to prolong his erection. Subsequent priapism developed, and the incarceration necessitated emergency intraoperative removal with a pneumatic orthopedic drill.

Figure 44-27. Fracture of the penis. Traumatic rupture of the corpus cavernosum, usually associated with sexual activity, results in a profound penile hematoma, most often requiring operative repair.

Genital bite wounds may be inflicted by humans during sexual activity or by animals. The predominant human oral bacterial organism in genital bite wounds is *Eikenella corrodens*; however, transmission of viral infections, including hepatitis and HIV is possible. Dog and cat bites may lead to pathogenic infections with *Pasteurella multocida* and anaerobic organisms. With animal bites, the possibility of rabies transmission must be considered.

Injuries to the female external genitalia may result from pelvic fractures, sexual assault, or straddle-type mechanisms. Hematomas and lacerations are the most common injuries. Physical examination includes evaluation for associated injuries of the vagina, urethra, bladder, and rectum. Screening for interpersonal violence should be considered in all women presenting with injuries to the external genitalia.

In children, blunt or penetrating injury to the external genitalia may be inflicted by straddle-type injuries or falls onto sharp objects. Child abuse should be considered and investigated when the explanation given for the event does not match the type of injury and objective physical findings. Examples include bruises that look like pinches, cigarette burns, or a penile injury reportedly caused by a falling toilet seat in a child who is too small to stand unsupported.

**Diagnostic Strategies**

A careful physical examination is usually sufficient to diagnose most blunt penile injuries. Retrograde urethrography is indicated in cases of suggested urethral injury, which should be considered in the presence of concomitant penile or scrotal hematoma, hematuria, or blood at the urethral meatus. Rarely, atypical presentations of penile fracture may require adjunctive imaging. Corpus cavernosography, ultrasound, and magnetic resonance imaging have all been advocated for this indication. The acquisition of penile imaging should occur in consultation with the treating urologist.

Unlike penile injuries, physical examination is frequently inadequate for the assessment of blunt scrotal trauma. Ultrasound is the test of choice owing to its greater than 95% sensitivity for testicular rupture when the diagnosis is based on the finding of a heterogeneous echo pattern of the testicular parenchyma with a loss of contour definition (Fig. 44-28). Scrotal imaging is rarely indicated after penetrating trauma because surgical exploration is usually warranted.

**Management**

Constricting devices must be promptly identified and removed, a procedure that can test the ingenuity of even the most experienced emergency physician (see Fig. 44-26). Various creative
techniques, using saws, metal cutters, or emery wheels, may be necessary to remove some metal objects. Reconstructive surgery of the penis may eventually be needed but is usually delayed until penile tissue viability has been determined. Fortunately, each corpora body has a separate blood supply and may be preserved even though the penile skin may slough and require skin grafting.

Superficial penile hematomas without rupture of the tunica albuginea and no immediate detumescence of the erect penis may be treated conservatively with the local application of ice and administration of nonsteroidal anti-inflammatory drugs (NSAIDs).12 Superficial lacerations of the penile and scrotal skin may be primarily approximated with 4-0 chromic or Vicryl absorbable suture. Patients with degloving penile injuries and scrotal skin loss should be treated by a urologist and plastic surgeon in the operating room with cleansing, débridement, and skin flaps or skin grafts.

With penile fracture, immediate surgical repair of the tunica albuginea defect (within 24–36 hours after injury) is indicated to maximize functional outcomes.12,44,46 Early surgical exploration and repair are recommended for most penetrating injuries to the penis.29 Penile amputation may be managed by reimplantation or local reshaping. Successful reimplantation may be achieved even up to 24 hours after amputation.43,44 The recovered amputated penis should be carefully wrapped in sterile, saline-moistened gauze and placed in a plastic bag. That bag is then placed in a second plastic bag containing ice. Hemostasis of a bleeding penile stump can usually be achieved with direct pressure.

After blunt scrotal trauma, surgical exploration is indicated for treatment of testicular rupture, large hematocele, traumatic torsion, and testicular dislocation. Testicular salvage rates are 80 to 90% when surgical exploration occurs within 72 hours and less than 50% when exploration is delayed beyond 72 hours.44 In patients with a sonographically normal, homogeneous-appearing testicle, exploration is not necessary.33 Testicular contusions are treated with bedrest, ice packs, NSAIDs, and urology follow-up. Surgical exploration is indicated in nearly all cases of penetrating scrotal trauma.45,49

Patients presenting with simple bite wounds within 6 to 12 hours after injury without gross contamination can be treated with irrigation and primary closure.43,44 Broad-spectrum antibiotic coverage with an agent such as amoxicillin-clavulanate is indicated. Grossly contaminated or infected wounds should be irrigated, covered with a sterile dressing, and managed in conjunction with the consulting urologist.

Human bite wounds represent a potentially serious polymicrobial infection. When cellulitis is present, immunocompromised patients should be admitted to the hospital for broad-spectrum IV antibiotic coverage for both aerobic and anaerobic organisms with an agent such as piperacillin-tazobactam. Immunocompetent hosts may be treated in the outpatient setting with broad-spectrum oral antibiotics, NSAIDs, and reevaluation in 48 hours.
## KEY CONCEPTS

- Diagnostic evaluation of the urinary tract is generally undertaken in retrograde fashion, that is, suggestion and elimination of urethral injury before bladder injury before ureteral or renal injury.
- Urethral injury is suggested by the presence of a pelvic fracture, blood at the urethral meatus, an abnormally positioned prostate on rectal examination, or evidence of a perineal, scrotal, or penile hematoma.
- Gross hematuria alone or in conjunction with a pelvic fracture is the absolute marker for significant bladder injury. Grossly clear urine in a trauma patient without a pelvic fracture virtually eliminates the possibility of bladder rupture.
- Bladder injury should be ruled out by retrograde cystography, which is more accurate than methods using anterograde contrast administration.
- Adults at risk for significant blunt renal injury have gross hematuria, microhematuria with shock, or a history of sudden deceleration. Children at risk for significant blunt renal injury have hematuria with greater than 50 RBCs/hpf or a history of significant deceleration.
- IV contrast-enhanced helical CT with delayed images at 10 minutes after contrast injection is the imaging modality of choice for suggested upper tract injury.

PERSPECTIVE

Injury to major arteries or veins is often life-threatening but invariably poses a threat to the viability of the affected limb. Historically, because of rapid blood loss, injury to major vessels was often quickly fatal in the field. Most patients who survived to reach a hospital had relatively minor vascular injuries. However, with the advent of modern emergency medical services systems with advanced extrication methods and rapid transport, more patients with major vascular injury reach the hospital alive. In addition, the incidence of penetrating civilian injuries from interpersonal violence and blunt injuries from motor vehicle–related trauma in the United States has increased dramatically during the past 50 years. Consequently, emergency physicians are frequently confronted with critically ill patients harboring overt or occult vascular injuries. Management of vascular injuries has evolved with advances in diagnostic methods and surgical techniques. Treatment of vascular injuries before and during World War II was simple ligation of the peripheral artery or vein involved. This approach resulted in limb amputation rates ranging from 40% for axillary artery injuries to 72% for popliteal artery injuries. During the Korean War, routine attempts to repair injured arteries decreased the amputation rate for popliteal injuries to 32%. During the Vietnam War, repair of penetrating axillary and popliteal artery injuries with routine angiography and improved surgical techniques resulted in decreases in the amputation rate to as low as 5 and 15%, respectively, which approach the current rate of amputation for civilian injuries. However, extrapolation of high-velocity military wound data to low-velocity civilian gunshot wounds may not be valid, and even lower rates might be expected with civilian wounds.

PRINCIPLES OF DISEASE

Pathophysiology

Blunt and penetrating types of trauma result in a similar spectrum of vascular injuries, although the mechanisms of injury differ. Although blunt vascular injuries are less common than penetrating injuries, they are often more severe and more commonly require amputation because of associated injuries to nerves, bone, and soft tissue. Certain mechanisms of injury, such as animal bites that crush and lacerate vessels, combine penetrating and blunt mechanisms.

Penetrating Trauma

Penetrating trauma from gunshot wounds results in the formation of a temporary cavity within distensible soft tissues with almost immediate recoil of these tissues. The size of the cavity and hence the degree of soft tissue injury depend directly on the velocity of the missile, as well as the tumble and yaw of the bullet. Consequently, gunshot wounds can cause direct arterial laceration or transection in addition to vascular injury at some distance from the track of the bullet. The latter injuries tend to be tears in the intima of an artery with subsequent thrombosis that may not become apparent for hours to months after the injury.

Stab wounds can cause vascular injury by complete or partial transection of vessels. Partial laceration of an artery may produce few symptoms of arterial insufficiency on initial evaluation but commonly results in delayed complications. The vascular structures at risk can be predicted more reliably with stab wounds than with gunshot wounds by taking into consid-
tery the anatomic location, the depth and direction of the wound, and the implement involved.

Shotgun wounds are less common than gunshot or stab wounds and cause injuries varying from minor soft tissue wounds to massive destruction of soft tissue and bone, depending primarily on the range from which the shotgun was fired. The presence of multiple missiles ranging from 9 or 10 (buck-shot) to dozens (birdshot) also complicates the evaluation of these injuries because of the many potential sites for vascular injury to occur. In addition, close-range shotgun wounds can cause significant blunt trauma to blood vessels, as well as a higher rate of bone and nerve injury than occurs with gunshot wounds. Migration of pellets proximally through the venous system to the heart or migration through an artery with subsequent distal occlusion has been reported frequently as a delayed complication.

Blunt Trauma

Blunt injury involves avulsion forces that can stretch vessels beyond their capacity or direct crushing injury that disrupts the vessel wall. Fracture fragments resulting from blunt extremity trauma can lacerate or entrap vessels. Vascular injury can range from small intimal tears to complete avulsion of arteries and nerves. Open avulsion injury of a limb is particularly severe because the skin is the final structure to tear, and once such tearing occurs, it is inevitable that vessels and nerves will be torn as well. Vascular injury must also be suspected in patients with massive soft tissue avulsion or crush injury, displaced long bone fractures, electrical or lightning injuries, and severe burns, as well as in those with compartment syndrome from trauma or prolonged immobilization as a result of stroke, coma, drug overdose, or other causes. Dog bites that are inflicted by large animals, such as those used by law enforcement, are particularly prone to arterial injury and wound complications. Collateral circulation may continue to perfuse the limb adequately, but injuries that occur proximal to the collateral branch point or that involve both the main trunk and collateral branches will preclude adequate flow.

Distal ischemia results from the inability of tissues to continue aerobic metabolism. Eventually, anaerobic metabolism consumes all substrate, thereby resulting in the accumulation of lactic acid. As ischemia progresses, cellular integrity is lost and irreversible cell death occurs. A vicious cycle of tissue edema and further impairment of the blood supply occurs. When no specific measures are taken to cool the limb, it is said that the limb is undergoing “warm ischemia” at room temperature. Although individuals may vary, 6 hours of complete warm ischemia is generally considered the point at which irreversible nerve and muscle damage begins to occur. After 6 hours of warm ischemia, 10% of patients will have irreversible damage; by 12 hours, 90% will have irreversible damage. Artificiially cooling the limb to just higher than freezing temperature will reduce the metabolic demands of unperfused tissues and greatly prolong the tissue’s tolerance of ischemia to 24 hours or more.

Two main types of vascular injury can result from trauma: occlusive injury (transection, thrombosis, and reversible spasm), in which all effective perfusion distal to the occlusion is lost, and nonocclusive injury (intimal flap, dissection, arteriovenous fistula [AVF], and pseudoaneurysm), in which some arterial flow continues past the injury.

Complete Occlusive Injury

Transection. The most common vascular injury is complete transection in which distal flow is effectively eliminated. Cleanly transected arteries will often retract and undergo spasm so that blood loss is minimized. With longitudinal arterial lacerations and venous injuries, blood loss cannot be limited by this means, and such injuries tend to result in greater blood loss. Pulsatile bleeding may lead to exsanguinating hemorrhage and shock.

Thrombosis. Intraluminal thrombosis (Fig. 45-1) may occur in an injured artery acutely (within 24 hours) or may be delayed for many months. Acute thrombosis is initiated by stasis resulting from compression of the artery or from a disruption in the intima of an artery that becomes a nidus for thrombus formation. As the thrombus propagates, complete occlusion of the vessel can occur. Delayed thrombosis can occur months to years after injury if the injured vessel heals with stricture formation and decreased blood flow distally, followed by stasis and clot formation.

Reversible Arterial Spasm. The precise cause and incidence of significant reversible arterial spasm after trauma are unknown. In many cases, the spasm occurs at some distance from the site of traumatic injury. In response to a traumatic stimulus, segmental narrowing of an artery may occlude the artery and produce distal ischemia. The spasm usually reverses with conservative treatment (topical warm saline or topical nitroglycerin paste), but prolonged spasm may require infusion of vasodilators such as nitroglycerin, calcium channel blockers, alpha blockers, nitroprusside, specific prostaglandin inhibitors, or warm saline. In many series, segmental arterial spasm is the most common arteriographic finding. However, it should never be assumed on clinical grounds that symptoms of ischemia are due to arterial spasm; that diagnosis is based on arteriographic results only.

Nonocclusive Injuries

Intimal Flap. An intimal flap occurs when there is a break in the intima of a vessel, generally from excessive stretch or concussive forces. Although flow is not altered by small flaps and the associated soft tissue wounds often appear benign initially, these intimal flaps may become a nidus for thrombosis that can
occur hours to months after the initial injury. However, most intimal flaps heal spontaneously, and asymptomatic injuries that do not disrupt perfusion of the limb can be treated conservatively.

**Pseudoaneurysm.** A true aneurysm contains all three layers of the vessel wall (intima, media, and adventitia) and rarely is caused by trauma. A pseudoaneurysm is formed following a tear in a vessel wherein the hemorrhage is contained by surrounding fascia and the resulting hematoma is gradually encased by a capsule of fibrous tissue, analogous in consistency to the adventitia of a normal vessel (Fig. 45-2). Because it is relatively thin walled, rupture of a pseudoaneurysm is a distinct possibility. In addition, because its diameter inevitably expands under arterial pressure over days to months, compression of adjacent tissue may result in neuropathy, venous obstruction with resultant peripheral edema and venous thrombosis, and even erosion into adjacent bone. The cavity of a pseudoaneurysm is in direct communication with the lumen of the vessel, so embolization of mural clots may produce distal arterial occlusion. Patients with pseudoaneurysm are commonly seen months to years later with symptoms of compression neuropathy or peripheral arterial embolism or for investigation of a soft tissue “tumor” that represents the growing aneurysm.

**Arteriovenous Fistula.** An AVF is formed when both the artery and an adjacent vein are injured. Higher pressure arterial flow is directed into the lower pressure vein, thereby diverting the blood supply to distal tissues and engorging the distal veins. Because the aperture of the fistula is often relatively narrow and thus results in turbulent flow, a bruit and palpable thrill are common diagnostic findings. Symptoms are primarily those of distal ischemia, but rarely high-output congestive heart failure may occur when large central vessels are involved. Symptoms are often delayed for months because it takes time for the fistula to mature.

**Compartment Syndrome.** Compartment syndrome is most common after crush injury or a long bone fracture but may also be seen after reperfusion of an ischemic limb. Initially, blood flow is diminished and the injury can be considered nonocclusive. Progressive edema elevates tissue pressure above capillary pressure, thus ending arterial perfusion and initiating a cascade of events that result in compartment syndrome. The risk for this complication is increased when ischemia time is prolonged; in the presence of combined arterial and venous injury; after ligation or repair of a major artery or vein; or in the presence of significant soft tissue injury, frequently concomitant with a long bone fracture. Smaller caliber vessels are compressed first, whereas larger vessels remain relatively patent and compartment pressure rarely exceeds arterial pressure, so pulses may be palpable until late in the course. If allowed to progress, however, all blood flow may end and the injury is then an occlusive one. After restoration of arterial flow to a previously ischemic limb, a cascade of reperfusion injury has been identified that results from release of oxygen free radicals, lipid peroxidation, and influx of intracellular calcium. These mediators give rise to progressive cellular damage, edema, and necrosis, thereby propagating the vicious cycle that increases compartment pressure. Consequently, frequent reexamination of the limb is indicated to assess compartment pressure after arterial repair.

### CLINICAL FEATURES

Detection and treatment of vascular injuries must take place within the context of the overall resuscitation of the patient according to established principles of trauma care. If the source of bleeding is readily identifiable, it is compressed with digital pressure. While control of active bleeding is being achieved in this manner, detection and treatment of other life-threatening injuries proceed concurrently. Peripheral vascular injury can occur coincident with other life-threatening trauma, which may take higher priority in resuscitating the patient. In other cases, peripheral vascular injury may be the most serious or only injury, and evaluation and management of this type of injury can proceed directly. Despite rapid transport to a hospital through a modern emergency medical service, injury to large central arteries and veins is still often fatal, and many of these deaths occur before medical contact. Patients who survive to reach the hospital may have obvious exsanguinating hemorrhage or only very subtle signs of vascular injury. Many patients have no evidence of injury but are considered at risk for vascular injury because of penetrating wounds in close proximity to major neurovascular bundles or because they have sustained high-risk injuries such as posterior knee dislocation. Patients who remain hypotensive after an initial fluid challenge may harbor an occult vascular injury if no other cause is found. In addition, patients with symptoms of intermittent claudication or with unexplained peripheral embolization and a history of previous trauma to the limb should be suspected of having occult arterial injury.

Peripheral vascular injury can be divided into three categories by physical examination: hard findings, soft findings, and asymptomatic high-risk wounds based on the mechanism of injury.

#### Hard Findings of Vascular Injury

Many patients have the classic “hard” findings of arterial injury, including pulsatile bleeding, loss of distal pulses, an audible bruit or palpable thrill indicative of an AVF, or an expanding or pulsatile hematoma. In addition, pallor or cyanosis and decreased temperature are common in a poorly
perfused extremity, and massive distention of distal superficial veins may indicate an AVF as arterial flow is directed into distensible veins. The incidence of arterial injury in patients with any hard finding is consistently greater than 90%,21,22 and the presence of these findings requires further investigation by emergency angiography or immediate surgical intervention, depending on the duration of warm ischemia and the overall status of the patient.

Soft Findings of Vascular Injury

An additional group of patients have “soft findings” of vascular injury, including a palpable but diminished pulse in comparison to the uninjured extremity, isolated peripheral nerve injury, history of severe hemorrhage in the field, unexplained hypotension, or a large nonpulsatile hematoma.20-22 The significance of prolonged capillary refill is controversial; some experts find it to be a reliable sign of vascular injury (when combined with a pulse deficit) and consider delayed capillary refill to be a valid soft sign of vascular injury. Others have found this sign to be a nonspecific and unreliable predictor of arterial injury.2,5 Delayed capillary refill by itself is insufficient to diagnose arterial injury, but in combination with other physical signs, it supports the diagnosis.

Isolated penetrating injury to a peripheral nerve is commonly associated with vascular injury because of the close proximity of these structures within the neurovascular bundles. Vascular injury occurs in 8 to 45% of cases of penetrating peripheral nerve injury.23,24 Conversely, vascular injuries have associated peripheral nerve injury in almost half of cases. It is sometimes difficult to distinguish whether the pain, paresthesias, or paralysis is due to a primary nerve injury, an associated vascular injury causing compression of the nerve, or compartment syndrome. In general, primary nerve injury occurs immediately at the time of injury, whereas vascular neuropathy occurs over minutes to hours after the injury. Up to 35% of patients with “soft” findings of vascular injury have positive angiographic studies, although only a small proportion of these injuries require emergency repair.20,24,25

High-Risk Injuries

The proximity of a penetrating wound to a neurovascular bundle is defined imprecisely. Various definitions include 1 cm, 1 inch, or 5 cm as constituting “proximity.” Certainly, penetrating wounds that occur within 1 cm of a major neurovascular bundle or whose presumed trajectory has crossed such a bundle (“proximity wounds”) are more likely to produce an occult vascular injury. Major neurovascular bundles include large limb arteries proximal to critical branch points, such as the axillary, brachial, common femoral, and popliteal arteries (Figs. 45-3 and 45-4).26 In addition, a small minority of patients with high-risk injuries, such as bites from large dogs or other animals, severely displaced fractures, crush injuries, or major joint dislocations (especially knee dislocation), will initially have occult vascular injury that may not be detected by physical examination. The risk of missing such injuries is that the traditional 6-hour window of warm ischemia time will be exceeded or the patient will experience delayed complications resulting in loss of the limb. For example, patients with intimal flaps may be completely asymptomatic initially but can subsequently be subject to arterial thrombosis. Similarly, pseudoaneurysms progressively enlarge to produce compression of adjacent structures but may be very small and undetectable on initial physical examination. Consequently, many centers routinely perform some ancillary confirmation of arterial patency in these cases.
History

In patients who achieve and maintain hemodynamic stability, a more comprehensive history can be obtained. Important historical points to note include the exact time and mechanism of the injury. The time of injury is important because of the significant morbidity that results from prolonged warm ischemia time. The mechanism is of clinical and often forensic importance in that the injury is frequently inflicted during an assault or other violent crime, in the context of domestic violence or physical abuse, or in association with work. Various mechanisms of injury may mandate special reporting and may alter the patient’s ultimate disposition. Certain types of injuries, such as crush or bite wounds, are particularly prone to complications. The occupation, avocation, and hand dominance of the patient are pertinent because a more aggressive strategy may be indicated in certain cases. Medical conditions that pose a risk of complications are important to note. Patients who are immunocompromised because of diabetes, acquired immunodeficiency syndrome, asplenia, cancer, or steroid use are at increased risk for infection and impaired wound healing. Patients with previous vascular insufficiency have more tenuous perfusion, are more susceptible to ischemia from elevated compartment pressure, and have a higher incidence of complications. As with most aspects of trauma care, patients whose sensorium is altered by head injury or intoxication, patients with spinal cord injury who cannot perceive pain, and those with significant painful distracting injuries will not reliably be able to report pain or paresthesias suggesting vascular insufficiency, so extra caution must be exercised in these cases.

Physical Examination

Surprisingly, in this era of increased reliance on technology, meticulous physical examination in combination with comparison of blood pressures in the affected and unaffected limbs has reemerged as the mainstay of diagnosis of vascular injury.21 Physical examination is directed at discovering evidence of local wound complications and distal ischemia suggestive of vascular injury. Palpation of pulses in the affected extremities is the initial step. A comparison of the strength and quality of the pulses between the injured limb and its uninjured counterpart is then made. Isolated detection of a pulse deficit distal to the site of injury is a finding that merits further investigation rather than immediate surgery because palpation of pulses is a relatively inaccurate means of predicting arterial injury. False-positive findings of a pulse deficit may occur because of shock, in which all pulses are diminished; congenital absence of a pulse in one extremity; preexisting vascular disease; or arterial spasm or compression. A false-positive finding of a pulse deficit occurs in 10 to 27% of cases.5,21 False-negative findings can occur with transmission of the pulse through a “soft clot,” past an intimal flap, or through collateral circulation. Distal pulses can persist in 6 to 42% of patients despite significant arterial injury.27 Compression of an artery by casts, splints, or dressings may produce a pulseless extremity, and these should be removed if evidence of ischemia occurs. Finally, although the pulse may be absent, the limb may be well perfused by collateral arterial supply, thus making repair of the arterial injury less compelling. Simultaneous palpation of the injured and unaffected limbs can detect relatively small differences in skin temperature that may suggest hypoperfusion. Testing two-point discrimination on the injured and unaffected limbs is similarly an effective means of detecting sensory deficits. Auscultation over the site of injury is an often-ignored examination that may reveal a bruit suggestive of an AVF. A bruit is audible in more than half of patients with an AVF.28 Repeated examination of the hematoma adjacent to the wound is indicated to determine whether it is expanding or pulsatile.

Despite the limitations just noted, reliance on the history and physical examination to triage patients into immediate surgery, angiography, and observation groups has been found to be relatively dependable, with a sensitivity of 92% and a specificity of 95%.21

■ DIAGNOSTIC STRATEGIES

The diagnostic strategy for detection of peripheral vascular injury must be tailored to the clinical situation. Patients with clearly evident major arterial injury (e.g., pulsatile hemorrhage from a penetrating wound with a cold, pulseless distal end of the extremity) may require emergency operative intervention without the potential benefit of any ancillary confirmation of their injury. Occasionally, the use of an intraoperative angiogram may be helpful in delineating the exact location and nature of the injury in patients taken directly to the operating room. However, delaying definitive treatment of an obvious arterial injury that is approaching the 6-hour limit of warm ischemia time to obtain an angiogram is ill advised.

Plain Radiography

Plain radiographs of the affected extremity are indicated to detect fractures, joint penetration, and foreign bodies. With gunshot wounds, the sum of the number of intact bullets seen on x-rays and the number of wounds in the body must be an even number. Failure to locate a bullet can result in unexpected complications. Rarely, bullets or shotgun pellets can migrate distally and produce vascular occlusion or migrate proximally through the venous system to the heart. These emboli are readily detected on plain radiographs if the search is vigilant.25,30 Lead bullets retained within a synovial joint can result in systemic absorption and elevated lead levels and should be removed electively.31-37

Pulse Oximetry

Several relatively simple noninvasive maneuvers can be performed at the bedside to elicit evidence of arterial injury. The use of pulse oximetry has been suggested as a means of identifying limb ischemia after trauma, but it has been found to be relatively insensitive for this purpose. Clearly, in the absence of a pulse, no reading can be obtained. As the technology of transcutaneous measurement of physiologic indices advances, measurement of tissue oxygenation by near-infrared spectroscopy to quantify muscle oxyhemoglobin may prove more useful in detecting vascular injury because these devices are portable, noninvasive and simple to use and appear to provide more accurate information than pulse oximetry.38-43

Hand-held Doppler

An inability to palpate pulses in an injured extremity should be verified by auscultation with a hand-held Doppler unit. Apart from the absence of any signal, arterial injury may be suggested by a change in the usual triphasic quality of the Doppler pulse to a biphasic or monophasic waveform as the pulse is “damped” by partial occlusion. Although more sensitive, auscultation of the pulse by Doppler is subject to the same types of limitations as is palpation of the pulse.
Ankle-Brachial Index and Arterial Pressure Index

Determination of the ankle-brachial index (ABI) or the arterial pressure index (API) has been well studied and provides more accurate information than physical examination alone. Systolic pressure is measured by inflating a standard blood pressure cuff proximal to the injury and recording hand-held Doppler systolic pressure distal to the injury. The process is repeated on the uninjured limb, and a ratio of injured to uninjured systolic pressure is calculated (API). Generally, a ratio less than 0.90 is considered abnormal and is an indication for further investigation. In several studies, an API less than 0.90 yielded a sensitivity of 95%, specificity of 97%, positive predictive value of 100%, and negative predictive value of 95%.

However, a few studies have found API to be less accurate, including one in which a cutoff of 0.90 resulted in a false-negative rate of nearly 40%; nevertheless, the use of an API ratio less than 0.90 can eliminate a large number of unnecessary angiograms for proximity wounds and increase the diagnostic efficiency of angiography or computed tomographic angiography (CTA) by limiting its use to high-yield cases.

Patients with an API of 0.90 to 0.99 merit observation for 12 to 24 hours for repeated physical examination and API measurements to detect evolving injury. Patients with a normal physical examination and normal ABI can be safely discharged from the emergency department provided there are no other injuries requiring admission.

Exclusive reliance on API to screen for arterial injury has significant limitations. Comparisons cannot be made when both limbs are injured or when severe soft tissue mashing precludes placing a blood pressure tourniquet or locating the artery to be measured with the Doppler unit. As with physical examination, the sensitivity of API is limited when an intimal flap allows near-normal flow or when collateral circulation is sufficient to produce near-normal systolic pressure, as in proximal injuries to the subclavian or iliac vessels. Certain arteries (e.g., the profunda femoris, profunda brachii, and peroneal arteries) normally do not produce palpable pulses, and API is of limited utility in these injuries. Shotgun wounds often have normal APIs despite multiple small arterial wounds; angiography is the preferred diagnostic modality in this group. As with angiography, API cannot detect venous injuries.

Despite the limitations previously noted, API has proved effective in screening patients with proximity wounds. The vast majority of injuries missed by API heal spontaneously. Those that do not heal are generally seen within 3 months with signs of arterial injury and can be repaired electively.

Ultrasound

The development of relatively small portable ultrasound (US) units has made possible direct visualization of both arterial and venous flow in major vessels. There are several different types of US that can detect vascular injury, and newer, more accurate techniques are being rapidly developed. B-mode (real-time) ultrasound is the most readily available form of US in portable units. It can easily visualize arterial pulsation in major vessels. Loss of pulsation distal to an obstruction or thrombosis is readily apparent. However, B-mode US cannot visualize certain anatomic areas accurately (subclavian and iliac vessels) because of overlying gas and is unreliable in detecting a fresh, relatively nonechogenic thrombus or hematoma. As blood liquefies within a hematoma, it becomes echoluent and more readily distinguishable from surrounding tissues.

Doppler US interprets sound moving toward or away from the transducer as flow. Venous flow is heard as a low-pitched hum, whereas arterial flow has a higher pitched triphasic quality. The combination of B-mode and Doppler US is called duplex US and has enhanced accuracy in examining blood vessels. Duplex scans showing a focal increase in peak systolic velocity suggest partial obstruction of the vessel. However, duplex scanning is slightly less accurate in detecting injuries that do not decrease flow, such as small pseudoaneurysms, AVF, and intimal flaps. Also, it is technically limited in examining certain anatomic areas, such as the profunda femoris and profunda brachii arteries and the iliac and subclavian vessels. Duplex US findings may be subtle, and as with other applications of US, its accuracy is highly operator dependent. Despite these limitations, the sensitivity of duplex US in comparison to standard angiography ranges from 83 to 100%, with a specificity of 99 to 100% and an accuracy of 96 to 100%.

Color flow Doppler converts Doppler echoes into quantitated visual signals. Flow toward the transducer is seen as red, and flow away from the transducer is seen as blue. The intensity of the color (the number of pixels on the screen) is proportional to flow through the vessel. Small prospective studies have indicated a high rate of accuracy in detecting arterial injury. Abnormal color flow is readily apparent, but more subtle injuries, such as intimal flaps and small pseudoaneurysms, are more difficult to identify. In addition, color flow Doppler is more accurate than standard venography in detecting major venous injuries. The overall sensitivity of color flow Doppler in detecting arterial injury is 50 to 90%, with a specificity of 95 to 99%. The sensitivity for detecting injuries requiring surgical repair is greater than 90%.

The use of intravascular US for examination of abdominal aortic aneurysms has been well documented. Although not yet applicable to smaller peripheral vessels, with further reduction in size of the transducers, this technique may eventually be applicable for peripheral vascular injury as well.

Computed Tomography and Magnetic Resonance Imaging

With a few important exceptions, computed tomography (CT) with contrast enhancement (CTA) has largely replaced catheter-based angiography for the detection of peripheral vascular injury in most trauma centers. Multidetector helical CT (MDCT) scanners have proven very accurate for diagnosis of peripheral vascular injury in multiple series with a sensitivity of 93 to 100% and specificity of 87 to 100% compared to catheter-based angiography. The advantages of CTA over catheter-based angiography are that it is noninvasive, readily available, less costly, and provides information on other injuries in the region being studied. However, there are several pitfalls in the use of MDCT angiography. Metallic artifact from bullets, orthopedic hardware, or other penetrating objects may obscure visualization of parts of a vessel. Venous injuries may be missed depending on the phase of the contrast. Due to the enhanced detail, accuracy, and speed of image acquisition with 64-256-slice CT scanners and the ability to perform three-dimensional reconstructions, reliance on this modality will likely increase in the future. Magnetic resonance imaging angiography has been described and accurately detects vascular injuries but has yet to prove clinically useful.

Arteriography

The policy of routinely exploring proximity wounds greatly improved the preservation of injured limbs in World War II. With the advent of arteriography, it became apparent that
many negative wound explorations could be avoided with routine arteriography. In a study using routine arteriography, the negative surgical exploration rate in patients with “soft signs” of arterial injury or with proximity wounds decreased from 84 to 2%.66 As a result, until recently, catheter-based contrast angiography has been the gold standard for diagnosing peripheral arterial injury, with a sensitivity of 99% and specificity of 97%.20

Beginning in the 1980s, the number of civilian penetrating wounds increased dramatically. Because of high cost, limited availability at all hours, and poor reimbursement rates, the policy of routine arteriography for proximity wounds has been questioned. From a practical perspective, the time required to mobilize the angiography team and perform the study may be several hours, thus making this option less desirable when dealing with the time limitations posed by arterial injury. In addition, arteriography has a small but measurable complication rate, including allergic reactions to contrast media, renal complications, hematoma formation, and false aneurysm formation at the site of cannulation. Finally, the clinical utility of the information provided by arteriography has become increasingly suspect in recent years as more of these injuries have been managed expectantly. Routine “exclusion” arteriography for proximity wounds detects unsuspected arterial injury in 0 to 21% of cases.25,66,67 However, relatively few of these patients require emergency surgery. In a series of 284 patients who underwent routine angiography for proximity wounds, 17% had unsuspected arterial injury detected, but only 1.8% (5 patients) required emergency surgical repair.68 In other series reporting on a total of 483 patients who underwent angiography for proximity wounds, only one arterial injury that required emergency repair was discovered.66,67 In the presence of “soft signs” of injury, the yield for angiograms increases to 29 to 35%, but many of these injuries do not require emergency repair and can be detected by noninvasive means.66 In addition, angiography results in an approximately 5% false-positive and false-negative rate compared with surgical exploration. Many of the injuries detected on angiography are due to reversible vasospasm or very small intimal defects that generally heal spontaneously. Consequently, angiography for proximity wounds can detect injury in up to 21% of cases but results in acute surgical intervention in only 0 to 4.4% of cases.66 Many centers now successfully manage proximity wounds by repeated physical examination over a 24-hour period and reserve CTA for those with abnormal physical findings or an ABI less than 0.9.66,73,74 Angiography is also limited in that it cannot detect major venous injuries, which are increasingly being repaired surgically. The use of angiography is difficult in children because of the small caliber of their vessels and a propensity for vasospasm induced by angiography. Consequently, physical examination and noninvasive methods are preferred for detection of vascular injury in young children.69

Digital subtraction angiography (DSA) has been used for detecting vascular injuries as well. DSA has been found to be more accurate than standard angiography for detection of extravasation and has the advantage of requiring the administration of a smaller load of contrast material. However, the field of view is much smaller with DSA than with standard angiography, thus making it technically difficult to study the entire course of a limb artery with DSA. Standard angiography is also more accurate than DSA in detecting intimal flaps and dissection.

Both traditional angiography and CTA have the advantage over other diagnostic techniques in that they can also be used to treat many lesions. Embolization of pseudoaneurysms, endovascular stent insertion to bypass a dissection or AVF, and injection of thrombolytic agents to dissolve thrombus are routinely performed via intra-arterial catheter. Because of increased reliance on endovascular treatment, many of the lesions detected by other means ultimately still require angiography.

■ TREATMENT

Initial treatment is directed at ensuring a patent airway and adequate air exchange before assessing the circulation. Once this is accomplished, active hemorrhage is controlled by direct digital pressure. Blind clamping of a bleeding vessel is not recommended because of the risk of crushing adjacent nerves; however, clamping a clearly visible vessel can be effective. The use of tourniquets is similarly discouraged because occlusion of veins results in increased compartment pressure and an increased risk for venous thrombosis.5 However, recent reports in the military literature have found the use of tourniquets for up to 6 hours to be safe and effective.74 In cases in which proximal and distal control of large vessel injuries cannot be readily achieved in the emergency department, insertion of a Foley catheter into the wound and inflation of the balloon with sterile water can temporarily tamponade the bleeding. Intravenous lines should not be started in the injured extremity because they may be ineffective in delivering resuscitation fluid and because extravasation from an injured vein may increase compartment pressure. Serial hemoglobin determinations may indicate unexpected blood loss from occult vascular injury. Patients with significant blood loss should have blood typed and crossmatched and may require immediate transfusion for stabilization. Patients with significant vascular injury often remain hypotensive despite such infusion and require further volume infusion or blood transfusion. Moribund patients with multiple severe injuries may require urgent amputation as part of their overall stabilization or extraction from wrecked automobiles. Between 50 and 70% of patients with severely mangled limbs require urgent amputation, especially if they have multisystem trauma.25

The issue of “hypotensive resuscitation” is controversial with regard to major vascular injuries. A tenuous clot can form in injured arteries and prevent further blood loss as long as the patient remains hypotensive. Once arterial pressure reaches a critical but variable point, the clot may be expelled and massive blood loss can ensue. Therefore, when the arterial injury is inaccessible for occlusion by direct pressure, the target blood pressure for resuscitation should be lowered to a systolic pressure of approximately 90 mm Hg. Overly aggressive and rapid fluid administration in the field or in the emergency department can produce transient intravascular hypervolemia and may ultimately increase the rate of blood loss. Close monitoring of vital signs and the total volume of fluid infused is indicated in these situations.

Once a vascular injury is identified, a specific diagnostic and therapeutic strategy can be developed that is consistent with the severity of the injury, the presence of other injuries, and the resources available. In hospitals without the ability to perform vascular repair, transfer to a trauma center should be initiated early. In cases in which the transfer will involve a delay of several hours, cooling the ischemic limb by packing it with ice will avoid exceeding the critical six-hour cutoff for warm ischemia.

Major Vascular Injuries

Major vascular injuries that compromise the viability of a limb must be repaired within 6 hours to avoid irreversible ischemic neuropathy and myonecrosis.5 Treatment of vascular injury
has changed dramatically in the past 10 years. Endovascular treatment with self-expanding stents is currently the preferred technique for repair of these injuries in stable patients, and the majority of arterial repairs in the United States are now done with this technique.\textsuperscript{76-78} In hemodynamically unstable patients, open surgical repair is still preferred. If other life-threatening injuries must be repaired first, a temporary polytetrafluoroethylene (PTFE) vascular shunt can be placed in the operating room to restore perfusion to a limb.\textsuperscript{79} These temporary PTFE shunts can be left in place for up to 24 hours before thrombosis begins to occur within the shunt. Major arterial transection or thrombosis is ideally repaired by end-to-end anastomosis if possible without placing undue tension on the suture line. If a larger segment of the artery is destroyed, interposition of a reverse saphenous vein graft is the preferred technique. PTFE grafts are suitable for grafting larger arteries if necessary, but they tend to occlude when used in smaller arteries (e.g., distal to the femoral or brachial arteries). Before completing the reanastomosis, a Fogarty catheter is passed through both ends of the repair to extract any thrombi that may have formed. The distal circulation is flushed with a dilute \(1:10\) solution of heparin or enoxaparin to prevent early clot formation. Systemic administration of heparin is usually contraindicated in major trauma patients. Assessment of distal perfusion and, in particular, compartment pressures is indicated frequently after repair and reperfusion of the limb. The use of broad-spectrum antibiotics is recommended before commencing a vascular repair.

Apart from excision of the affected arterial segment and repair of the vessel, less invasive techniques have been developed to manage pseudoaneurysms. Percutaneous embolization with Silastic beads, gel clot emboli, or thrombogenic coils is often successful.\textsuperscript{80} Placement of an endovascular stent can exclude the aneurysm and is also a successful alternative to open repair.\textsuperscript{81} Similarly, repair of an AVF can be undertaken through open surgical ligation of the fistulous connection, by endovascular placement of a stent to exclude the fistula, or by percutaneous embolization of the fistulous tract.\textsuperscript{80}

### Late Complications

Despite timely optimal repair of arterial injuries, approximately 21\% of patients experience delayed complications requiring further surgical intervention, including delayed amputation. The most common of such complications is delayed thrombosis, which often occurs after many months as stenosis at the repair site progresses. Other complications include intermittent claudication, chronic pain or edema of the limb, and aneurysm formation in the graft.\textsuperscript{82}

### Venous Injuries

Venous injuries may be primarily ligated if the condition of the patient cannot tolerate prolongation of surgery. However, the current trend is to repair major venous injuries if possible, particularly in the lower extremity, because wound healing is improved and the incidence of compartment syndrome, venous thrombosis, pulmonary embolism, and chronic edema is decreased.\textsuperscript{83,85} Extensive venous collaterals in the upper extremity make surgical repair less compelling.

The timing of repair of a vascular injury when associated with complex fractures requiring fixation is controversial. Historically, the fracture was repaired first to give a more accurate measurement of limb length and the length of graft required for vascular repair and because of fear that manipulation of long bones during reduction might damage the vascular repair. However, the need for postoperative fasciotomy is higher in these patients than in those who undergo vascular repair first (80 vs. 36\%), and vascular repair is limited by warm ischemic time.\textsuperscript{86} Currently, in most centers, vascular repair is prioritized over orthopedic repair, although temporizing PTFE shunts may be used to restore perfusion during fracture repair.

### Minor Vascular Injuries

Increasingly, minor nonocclusive vascular injuries are being treated expectantly. Criteria for observation of vascular injuries include low-velocity missile wounds, intact distal circulation, absence of active hemorrhage, and minimal arterial wall disruption on angiography if performed. Angiographic or CTA findings meeting these criteria include intimal flaps extending less than 5 mm and pseudoaneurysms smaller than 5 mm in diameter.\textsuperscript{25,68,87} Follow-up of these injuries with repeat angiography or US reveals that approximately 85\% resolve spontaneously.\textsuperscript{68} Patients meeting these criteria can be monitored as outpatients for 3 months, with repeat physical examination and US to detect delayed complications.\textsuperscript{25,68,87} However, almost all pseudoaneurysms ultimately require repair and, once discovered, should be repaired electively rather than undergoing continued observation. Failure to detect and repair occult arterial injuries in children often results in severe differential limb growth, and thus a more aggressive policy of repairing any arterial injury that causes even a relatively minor decrease in blood flow to a child’s growing limb may be justified.

### Specific Injuries

#### Upper Extremity

##### Subclavian Artery and Vein

Subclavian artery injuries are uncommon and represent 1 or 2\% of all vascular trauma.\textsuperscript{80} Isolated injury to the subclavian vein is more common than isolated arterial injury, but in almost half the cases both the vein and the artery are injured.\textsuperscript{80} The vast majority (95–99\%) are penetrating wounds, and because of massive hemorrhage, these injuries are often lethal before arrival at a hospital. Mortality in those who reach the hospital alive averages 15\%, but overall mortality as high as 75\% has been reported.\textsuperscript{80,81} Interestingly, morbidity is higher with a blunt mechanism, whereas mortality is higher with penetrating wounds.\textsuperscript{26} The right subclavian artery arises from the brachiocephalic artery, and the left arises from the arch of the aorta. From their origin, they course posterior and inferior to the clavicles to the outer margins of the first ribs, where they become the axillary artery and vein. The left subclavian rises higher than the right and extends into the root of the neck.\textsuperscript{26}

The clinical manifestation is that of hemorrhagic shock in 77\% of cases. Occasionally, unsuspected subclavian vascular injury is discovered at thoracotomy performed for excessive blood loss from a chest tube.\textsuperscript{89} Approximately 60\% have an associated pneumothorax or hemothorax, and additional injury to mediastinal and spinal structures is relatively common.\textsuperscript{88} Symptoms of limb ischemia may be apparent with absent radial and brachial pulses. However, pulses are completely absent in only 33\% of cases because collateral flow from the thyrocervical trunk may provide sufficient perfusion to avoid the symptoms and signs of ischemia.\textsuperscript{89} Neurologic deficits in the upper extremity occur in more than half of patients. The most severe of these injuries is disruption of the brachial plexus, which occurs in almost 50\% of patients with blunt injury.\textsuperscript{29}

In a series of 100 cases of subclavian artery injury, the combination of physical examination and chest x-ray findings
suggestive of subclavian injury (hemotherax, pneumothorax, apical pleural cap, or wide mediastinum) was 100% sensitive and could have eliminated the need for 69% of the arteriograms obtained. If the patient’s clinical condition permits, angiography can provide an accurate diagnosis and can locate the injury precisely.  

US techniques are also relatively inaccurate in detecting subclavian injuries because of interference by overlying gas-filled lung tissue. Therefore, in cases in which the clinical diagnosis is equivocal (“soft signs” of injury or proximity wounds), arteriography (CTA or catheter based) is required to detect the injury. Immediate proximal and distal control of the subclavian artery is very difficult. An incision along the course of the clavicle is recommended but often needs to be extended to a sternotomy. If primary reanastomosis is not possible, synthetic grafts are usually successful but have a tendency to fracture over time due to the wide range of motion at the shoulder and resultant compression of the graft by the first rib and clavicle.

Blunt subclavian injuries are often associated with clavicular fracture or dislocation. Isolated first rib fracture is rarely combined with vascular injury unless posterior displacement occurs. However, first rib fracture in association with other major injuries, such as a wide mediastinum on chest x-ray, an expanding hematoma, an upper extremity pulse deficit, or a brachial plexus injury, is accompanied by arterial injury in 24% of cases and merits investigation by angiography or CTA. Several cases of shear injury of the subclavian artery have been reported to result from a loose shoulder restraint of a seat belt. Isolated first rib fracture is rarely combined with vascular injury unless posterior displacement occurs. However, first rib fracture in association with other major injuries, such as a wide mediastinum on chest x-ray, an expanding hematoma, an upper extremity pulse deficit, or a brachial plexus injury, is accompanied by arterial injury in 24% of cases and merits investigation by angiography or CTA. Several cases of shear injury of the subclavian artery have been reported to result from a loose shoulder restraint of a seat belt. Overall, blunt subclavian artery injuries have a higher morbidity than penetrating injuries because of higher rates of limb amputation and associated brachial plexus injury.

Subclavian vein injuries are even more lethal than those to the artery. In addition to massive blood loss, there is a relatively high risk of massive air embolism, which is frequently fatal in association with penetrating subclavian vein injuries.

**Axillary Artery and Vein**

Injury to the axillary vessels constitutes 3 to 9% of all vascular injuries and is divided nearly equally between penetrating and blunt mechanisms. Forceful reduction of a chronically dislocated shoulder is a common iatrogenic cause of axillary artery injury. The axillary artery courses from the lateral border of the first rib to the inferior border of the teres major muscle, where it becomes the brachial artery. The axillary vein runs medial to the artery. The extensive anastomotic arterial connections around the shoulder joint usually permit good collateral flow and up to half of these patients will have palpable pulses as a result of collateral circulation. Because of the close proximity of the brachial plexus and the axillary vessels, significant denervation of the upper extremity can occur. Near-avulsion injuries resulting in scapulothoracic dissociation invariably produce severe disruption of the brachial plexus and often ultimately result in amputation despite successful vascular repair. There is a high rate of amputation for the combination of axillary vascular and brachial plexus injury, mainly because the presence of a flap limb results in amputation for placement of a prosthesis. In addition, patients with a flap limb have a 40-fold increased rate of suicide.

**Brachial Artery**

The brachial artery continues from the lower border of the teres major muscle and divides into the radial and ulnar arteriies at the level of the proximal aspect of the radial head. The median and ulnar nerves and the basilic vein are in close proximity to the brachial artery. The profunda brachii artery is a major branch that arises slightly after the origin of the brachial artery and often contributes good collateral flow if the brachial artery is injured distal to this branch point. Brachial artery injuries occur as a result of penetrating trauma, humeral shaft fracture, elbow dislocation, or animal bites. They are the most common major vascular injuries in the upper extremity. In 75% of cases, the radial pulse is absent. Studies have shown that limb salvage rates have improved to nearly 100% due to efficient out-of-hospital transport, improved surgical techniques, and shorter time to first antibiotic dose. Repair is indicated in all cases because the amputation rate is high with ligation.

**Forearm Arteries**

The radial artery begins in the cubital fossa and runs superficially to the distal end of the radius, where it ultimately joins the deep branch of the ulnar artery to form the deep palmar arch of the hand. The ulnar artery begins in the cubital fossa and runs with the ulnar nerve anterior to the flexor retinaculum, at which point it joins the radial artery to form the superficial palmar arch of the hand.

Injuries detected by arteriography or US that are below the bifurcation of the arterial supply in the upper extremity do not need to be repaired unless there are signs of ischemia in the hand; hard signs of arterial injury such as an expanding hematoma, pseudoaneurysm, or AVF; or injury to both radial and ulnar arteries. However, some authors recommend repairing all these injuries because of the risk of intermittent claudication or cold intolerance in patients who have one artery ligated. Certain patients are almost exclusively dependent on the ulnar arterial supply to the hand because of an underdeveloped deep palmar arch. Clearly, ulnar artery injuries must be repaired in these patients. Compartment syndrome in the forearm is common after repair of proximal arteries and veins and may require fasciotomy.

**Lower Extremity**

**Iliac Artery and Vein**

Given the intra-abdominal course of the iliac vessels, virtually all these injuries have associated trauma to the small or large intestine, bladder, solid viscera, or bony pelvis. The common and external iliac arteries are injured with equal frequency and more often than the internal iliac vessels. In moribund patients, an initial “damage control” laparotomy with temporary vascular shunting of the iliac vessels is often necessary as resuscitation continues. After the patient has overcome lactic acidosis, hypothermia, and coagulopathy, a second definitive repair can be undertaken. Surprisingly, the incidence of infection of synthetic or autologous grafts is rather low despite the high degree of bacterial contamination associated with perforation of a hollow viscus. Distal ischemic complications occur in approximately one third of repaired iliac arteries, and subsequent amputations are required in up to 18%.

**Femoral Artery and Vein**

The external iliac vessels become the common femoral vessels at the inguinal ligament. After giving off the profunda femoris artery in the femoral triangle, the femoral artery continues as the superficial femoral artery almost vertically to the adductor tubercle of the femur and enters the popliteal fossa as the
popliteal artery. There are extensive proximal collaterals around the hip joint, including the gluteal, obturator, and pudendal branches of the iliac artery.\textsuperscript{26}

Femoral artery and vein injuries are the most common vascular injuries seen in major trauma centers. Common femoral artery injury occurs as a result of intertrochanteric hip fracture, hip dislocation, and iatrogenic injury from the placement of arterial catheters or from hip replacement surgery, although 86\% of femoral artery injuries are due to penetrating wounds.\textsuperscript{18} Ligation of the common femoral artery culminates in amputation of the lower extremity in 80\% of cases, so repair should be attempted in all cases. Experimental data indicate that the use of \textit{N}-acetylcysteine may reduce the degree of ischemia after femoral artery injury and help reduce the high rate of amputation.\textsuperscript{99} Penetrating wounds of the thigh result in femoral artery injury in 6.2\% of cases, and up to 40\% of these injuries are clinically occult. A medial or anteromedial wound track is present in virtually all these cases, and some centers routinely perform angiography on these medial wounds.

**Popliteal Artery and Vein**

The popliteal artery gives off the genicular branches in the popliteal fossa and then divides into the anterior and posterior tibial arteries at the lower border of the popliteus muscle. The peroneal artery arises from the posterior tibial artery slightly after its origin. The anterior and posterior tibial arteries and the peroneal artery form the trifurcation of the popliteal artery, and each runs with a corresponding vein and nerve in different compartments of the leg.\textsuperscript{26}

The most common cause of popliteal artery injury is posterior knee dislocation in which bony elements directly lacerate or cause thrombosis of the artery. Displaced fractures of the knee, particularly tibial plateau fractures, may also result in popliteal artery injury. Anterior knee dislocations may cause excessive stretch on the popliteal vessels that can culminate in arterial thrombosis, but this injury is relatively rare. Overall, knee dislocation results in popliteal artery injury in 25 to 33\% of cases.\textsuperscript{100} Up to 40\% of these injuries may be clinically occult, and diagnosis is delayed in up to 40\% of cases,\textsuperscript{2} although other series note that more than two hard signs of ischemia occur immediately in 71 to 94\%.\textsuperscript{43} Twenty-five percent of cases have an associated injury to the peroneal and posterior tibial nerves. In half the cases, the knee dislocation may reduce spontaneously, leaving little evidence of the original trauma, particularly in obtunded patients.\textsuperscript{101} Patients showing complete ligamentous disruption of the knee on physical examination should be suspected of having a spontaneously reduced knee dislocation. Hemarthrosis may also be absent if the joint capsule is torn because blood can track into the fascial planes of the leg.

No consensus has been reached on the diagnostic approach to detect popliteal artery injury resulting from documented or suspected knee dislocation. There are three possible strategies, and each has proponents and detractors. The first option is to perform routine arteriography on every case of knee dislocation.\textsuperscript{102,103} The second is to perform arteriography on selected cases in which vascular injury is not certain despite the combination of physical signs, abnormal ABI measurement, or findings on noninvasive tests such as color flow Doppler, duplex scan, or CTA.\textsuperscript{104} The third option is to rely completely on these physical findings and ABI. If both these findings are normal, advocates of this approach claim 100\% negative predictive value for vascular injury that requires surgery.\textsuperscript{105,106} The choice of these options is institution specific, but most centers continue to use angiography in selected cases. Abnormal ABI and US (duplex and color flow Doppler) have been found to be very accurate in detecting popliteal injuries, and many centers reserve angiography or CTA for cases in which noninvasive tests result in equivocal findings. As a general rule, high-energy mechanisms of trauma (e.g., auto vs. pedestrian and motor vehicle collision) and posterior knee dislocations are more likely to produce popliteal artery injury than are low-energy mechanisms (e.g., sports injuries), and a more aggressive diagnostic approach (i.e., angiography or CTA) may be warranted in such cases. However, patients with penetrating trauma and more than one hard sign of popliteal artery injury can be taken directly to the operating room for repair because delaying these cases to obtain an angiogram is \textit{“superfluous, unnecessary, costly, and potentially dangerous.”}\textsuperscript{106} Patients with blunt trauma can have false-positive hard findings generated by soft tissue swelling and external arterial compression, and these patients should undergo diagnostic testing first to confirm arterial injury. The amputation rate for popliteal injuries was as high as 40\% in the past, but current rates are lower. In one large series, the amputation rate was 20\%, but a high rate of permanent disability was found at 2-year follow-up.\textsuperscript{102} Another series reported no amputations with modern diagnostic and repair techniques.\textsuperscript{106} Factors that place patients at higher risk of amputation include severe marling of the extremity or delay in repair exceeding 8 hours of warm ischemia time.\textsuperscript{101} Because of the high incidence of compartment syndrome with lower leg injuries, fasciotomy is required in 36 to 62\% of cases, and some centers routinely perform fasciotomy in all such cases.\textsuperscript{106} Approximately two thirds of patients with popliteal artery injury will have persistent deficits caused by peripheral nerve injury, chronic ischemia, or amputation.

**Lower Leg Arteries**

The popliteal artery divides into three branches—the anterior and posterior tibial and the peroneal arteries at the inferior margin of the popliteal fossa. Injuries below the trifurcation at the knee may need repair if hard signs of arterial injury are apparent in the foot or if two of the three arteries are occluded on angiography.\textsuperscript{25} However, vascular injuries in the lower part of the leg are notorious for causing compartment syndrome and need to be monitored closely. Amputation is usually due to a combination of soft tissue, nerve, and bone injuries. If significant injury to all three of these tissues is present, the amputation rate may reach 54\%.\textsuperscript{25,109} The combination of orthopedic and vascular injury, particularly as a result of crush injury, and shock on initial evaluation culminates in amputation in 35\% of cases and should be considered a poor prognostic sign for limb viability.\textsuperscript{110}

\section*{DISPOSITION}

Patients with confirmed injury to major vessels, equivocal findings on diagnostic tests, or symptoms of limb ischemia must be admitted to the hospital for further investigation or observation. Consultation with a vascular surgeon is indicated as soon as vascular injury is strongly suspected or the need for emergency operative repair established. Patients who are unstable because of vascular or other injuries may undergo further investigation or exploration in the operating room. If the treating hospital is incapable of performing vascular surgery or appropriate investigations, transfer to a trauma center should be initiated. Delaying transfer for angiograms of proximity wounds in centers that are incapable of acting on positive results is unwise because it often delays definitive care beyond the safe limits of warm ischemia time.
The overall condition of the patient determines the extent of diagnostic study and stabilization in the emergency department. Critical patients may require immediate surgery, which should not be delayed for confirmatory study of obvious vascular injury.

Arterial injury may be readily apparent or clinically occult. Up to 21% of proximity wounds show arterial injury on angiography. Similarly, various US modalities and abnormal APIs frequently detect clinically unapparent vascular injuries.

Symptoms of arterial injury may be delayed by hours to months after the initial injury. Late onset of symptoms suggests delayed thrombosis, pseudoaneurysm or AVF formation, compartment syndrome, or intermittent claudication resulting from stenosis or reliance on small-caliber collateral vessels for arterial perfusion.

Reperfusion injury can occur after restoration of arterial flow and result in compartment syndrome. Frequent reexamination of the reperfused limb is indicated in the postoperative period.

Compartment syndrome frequently develops in limbs with arterial injury, and fasciotomy is often required.

CT angiography is playing an increasing role in the diagnosis of vascular injury and is increasingly replacing catheter-based angiography for this purpose.

Many vascular injuries are amenable to endovascular treatment with self-expanding stents. This results in fewer complications, lower cost, and earlier discharge from hospital.
CHAPTER 46  General Principles of Orthopedic Injuries

Joel M. Geiderman and Dan Katz

■ MANAGEMENT PRINCIPLES

Patients with orthopedic injuries and nontraumatic musculoskeletal disorders compose a large portion of the more than 100 million patients who present annually to U.S. emergency departments (EDs). Although only rarely life-threatening, orthopedic injuries may threaten a limb or its function, and accurate early diagnosis and treatment can avert long-term complications. Many of these injuries can and should be treated definitively by the emergency physician. Consultation with an orthopedist should be sought for the treatment of most long bone fractures, open fractures, and injuries with neurovascular compromise and for follow-up of certain patients initially treated in the ED.

Orthopedic injuries often occur as a result of accidents (industrial or otherwise) and frequently involve young, otherwise healthy, working individuals. Accurate initial diagnosis, treatment, and documentation assume great importance medically and economically. Many problems can be avoided if the following 10 general principles are kept in mind:

1. Most orthopedic injuries can be predicted by knowing the chief complaint, the age of the patient, the mechanism of injury, and an estimate of the amount of energy delivered.
2. A careful history and physical examination predict radiographic findings with a high degree of accuracy. A presumptive diagnosis prior to a radiographic study may prompt the physician to order special views required to correctly diagnose an injury. Many fractures were accurately described before the advent of roentgenology.
3. If a fracture is suggested clinically, but radiographic films appear negative, the patient should initially be treated with immobilization as though a fracture were present.
4. Criteria for adequate radiographic studies exist; inadequate studies should not be accepted.
5. Radiographic studies should be performed before attempting most reductions except when a delay could be potentially harmful to the patient or in some field situations.
6. Neurovascular competence should be checked and recorded before and after all reductions and following application of immobilization.
7. Patients must be checked for the ability to ambulate safely before discharge from the ED and should not be discharged unless this can be established.
8. Patients should receive explicit aftercare instructions before leaving the ED, covering such areas as monitoring for signs of neurovascular compromise or increasing compartment pressure, cast care, weight bearing, crutch use, and an explicit plan and timing for follow-up.
9. In a patient with multiple trauma, noncritical orthopedic injuries should be diagnosed and treated only after other more threatening injuries have been addressed.
10. All orthopedic injuries should be described precisely and according to established conventions. When communicating with an orthopedic consultant, this may affect decisions regarding disposition of a patient and operative versus nonoperative management.

■ PHYSICAL EXAMINATION

■ FRACTURES

Fracture Nomenclature

Describing orthopedic injuries using precise language according to established convention enables accurate, clear communication with other parties. Terms commonly used to describe a fracture are listed in Box 46-1. A fracture is a break in the continuity of bone or cartilage. Clinically a history of loss of function, pain, tenderness, swelling, abnormal motion, and deformity suggests a fracture. Radiographic studies are the mainstay of diagnosis and are usually, although not always, confirmatory. At times, special views, radionucleotide bone scans, computed tomography (CT), or magnetic resonance imaging (MRI) are necessary to confirm a clinical impression. These studies should be considered when the clinical evidence is at odds with the findings of routine radiography.

General Descriptors

Description of a fracture should begin by stating whether the fracture is closed or open (less desirable terms are simple or compound). In a closed fracture, the skin and soft tissue overlying the fracture site are intact. The fracture is open if it is exposed to the outside environment in any manner. This exposure may be as obscure as a puncture wound or as gross as splintered bone protruding through the skin. It is sometimes difficult to determine whether a small wound in proximity to a fracture actually communicates with that fracture. Some physicians advocate probing such a wound with a blunt sterile swab to
### Table 46-1 Common Fracture Names and Their Origins

<thead>
<tr>
<th>FRACTURE EPONYM</th>
<th>DESCRIPTION</th>
<th>COMMENT</th>
</tr>
</thead>
<tbody>
<tr>
<td>Aviator’s</td>
<td>Vertical fracture of the neck of the talus with subtalar dislocation and backward displacement of the body</td>
<td>First described in flyers during World War I. Arises from forced dorsiflexion of the foot in flying accidents and in traffic accidents after a head-on collision</td>
</tr>
<tr>
<td>Barton’s</td>
<td>Intra-articular fracture-dislocation of the wrist</td>
<td>Considered complicated and unstable. Requires surgical reduction in most cases. Described by Barton in 1838 before the advent of radiography</td>
</tr>
<tr>
<td>Dorsal Barton’s</td>
<td>Oblique intra-articular fracture of the dorsal rim of the distal radius with displacement of the carpus along with the fracture fragment</td>
<td>Results from high-velocity impact across the articular surface of the radiocarpal joint, with the wrist in dorsiflexion at the moment of impact</td>
</tr>
<tr>
<td>Volar Barton’s</td>
<td>Wedge-shaped articular fragment sheared off the volar surface of the radius (volar rim fracture), displaced volarly along with the carpus</td>
<td>Similar mechanism as dorsal Barton’s but with wrist in volar flexion at time of injury. Also referred to as a reverse Barton’s. Much rarer than dorsal Barton’s</td>
</tr>
<tr>
<td>Bennett’s</td>
<td>Oblique fracture through base of the first metacarpal with dislocation of the radial portion of the articular surface</td>
<td>Usually produced by direct force applied to the end of the metacarpal. Dorsal capsular structures disrupted by the dislocation. Marked tenderness along medial base of thumb</td>
</tr>
<tr>
<td>Bosworth</td>
<td>Fracture-dislocation of the ankle resulting in the fibula being entrapped behind the tibia</td>
<td>Rare injury, produced by a severe external rotation force applied to the foot. Physical examination reveals foot severely externally rotated in relation to the tibia</td>
</tr>
<tr>
<td>Boxer’s</td>
<td>Fracture of the neck of the fourth or fifth metacarpal</td>
<td>Results from striking a clenched fist into an unyielding object, usually during an altercation, or against a wall, out of frustration or anger</td>
</tr>
<tr>
<td>Chance’s</td>
<td>Vertebral fracture, usually lumbar, involving the posterior spinous process, pedicles, and vertebral body</td>
<td>Caused by simultaneous flexion and distraction forces on the spinal column, usually associated with use of lap seat belts. Anterior column fails in tension along with the middle and posterior columns. May be misdiagnosed as a compression fracture</td>
</tr>
<tr>
<td>Chauffeur’s</td>
<td>Solitary fracture of radial styloid</td>
<td>Occurs from tension forces sustained during ulnar deviation and supination of the wrist. Name derives from occurrence in chauffeurs who suffered violent, direct blows to the radius incurred while turning the crank on a car, only to have it snap back, during previous eras</td>
</tr>
<tr>
<td>Clay shoveler’s</td>
<td>Fracture of the tip of the spinous process of the sixth or seventh cervical vertebra</td>
<td>First described in Australian clay shovellers who sustained a fracture of the spinous process by traction as they lifted heavy loads of clay</td>
</tr>
<tr>
<td>Colles’</td>
<td>Fracture of the distal radius with dorsal displacement and volar angulation, with or without an ulnar styloid fracture</td>
<td>Most common wrist fracture in adults, especially in the elderly. Results from fall on an outstretched hand. Also known as silver fork deformity, which accurately describes the gross appearance in the lateral view. First described by Colles in 1814, before the advent of radiography</td>
</tr>
<tr>
<td>Cotton’s</td>
<td>Trimalleolar fracture</td>
<td>Fracture of the lateral malleolus, the posterior malleolus, and either a fracture of the medial malleolus or a disruption of the deltoid ligament with visible widening of the mortise on ankle radiograph</td>
</tr>
<tr>
<td>Dashboard fracture</td>
<td>Fracture of the posterior rim of the acetabulum</td>
<td>Named for mechanism of injury: a seated passenger striking the knee on a dashboard, driving the head of the femur into the acetabulum</td>
</tr>
<tr>
<td>Dupuytren’s</td>
<td>Fracture-dislocation of the ankle</td>
<td>Results from a similar mechanism as the better known Maisonneuve fracture (i.e., external rotation of the ankle), resulting in either deltoid ligament rupture or medial malleolus fracture, diastasis of the inferior tibiofibular joint, and indirect fracture of the fibular shaft. Maisonneuve was the student of Dupuytren</td>
</tr>
<tr>
<td>Essex-Lopresti</td>
<td>Fracture of radial head with dislocation of distal radioulnar joint</td>
<td>Results from longitudinal (axial) compression of the forearm</td>
</tr>
<tr>
<td>Galeazzi’s</td>
<td>Fracture of the shaft of the radius with dislocation of the distal radioulnar joint. Ligaments of inferior radioulnar joint are ruptured and head of ulna displaced from ulnar notch of the radius</td>
<td>Results from fall on outstretched hand, with the wrist in extension and the forearm forcibly pronated. Inherently unstable with tendency to redisplace after reduction</td>
</tr>
<tr>
<td>Hangman’s</td>
<td>Fracture-dislocation of atlas and axis, specifically of pars interarticularis of C2 and disruption of C2-3 junction. Separation occurs between second and third vertebral bodies from anterior to posterior side</td>
<td>Results from extreme hyperextension during abrupt deceleration. Most common cause is the forehead striking the windshield of a car during a collision. A bit of a misnomer in that hanging usually produces death by strangulation rather than cord damage</td>
</tr>

<td>COMMENT</td>
</tr>
<tr>
<td>---------------------</td>
<td>-----------------------------------------------------------------------------</td>
<td>-------------------------------------------------------------------------</td>
</tr>
<tr>
<td>Hume</td>
<td>Fracture of the proximal ulna associated with forward dislocation of the head of the radius</td>
<td>Essentially a high Monteggia injury</td>
</tr>
<tr>
<td>Jefferson</td>
<td>Burst fracture of ring of C1, or atlas</td>
<td>Axial loading results in a shattering of the ring of the atlas.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Decompressive type of injury. Associated with disruption of transverse ligament; an unstable injury</td>
</tr>
<tr>
<td>Jones’</td>
<td>Transverse fracture of the metatarsal base, occurring at least 15 mm distal to the proximal end of the bone, distal to the insertion of the peroneus brevis</td>
<td>Should not be confused with the more common avulsion fracture of fifth metatarsal styloid, produced by avulsion at the insertion of the peroneus brevis. Jones described the fracture that bears his name in 1902, after suffering the injury himself while dancing</td>
</tr>
<tr>
<td>Le Fort</td>
<td>Maxillary fracture</td>
<td>Types I, II, and III (see Chapter 39)</td>
</tr>
<tr>
<td>Le Fort-Wagstaffe</td>
<td>Avulsion fracture of the anterior cortex of the lateral malleolus</td>
<td>Rare pull-off injury of the fibular attachment of the anterior tibiofibular ligament</td>
</tr>
<tr>
<td>Lisfranc’s</td>
<td>Fracture located around the tarsometatarsal</td>
<td>Lisfranc, a field surgeon in Napoleon’s army, described an amputation performed through the tarsometatarsal joint in a soldier who caught his foot in a stirrup when he fell off his horse. Since then, the joint has borne his name</td>
</tr>
<tr>
<td>Maisonneuve</td>
<td>Fracture of proximal third of fibula associated with rupture of the deltoid ligament or fracture of the medial malleolus and disruption of the syndesmosis</td>
<td>Results from external rotation of the ankle with transmission of forces through syndesmosis; proximally the force is relieved by fracture of the fibula. Described experimentally in 1840, before radiography</td>
</tr>
<tr>
<td>Malgaigne</td>
<td>Fracture of the ilium near the sacroiliac joint with displacement of the symphysis, or a dislocation of the sacroiliac joint with fracture of both ipsilateral pubic rami</td>
<td>Resultant pelvic injury is unstable. Described by Malgaigne, based on clinical findings, in 1847</td>
</tr>
<tr>
<td>March</td>
<td>Fatigue, or stress, fracture of the metatarsal</td>
<td>Arises from long marches or other repetitive use trauma (e.g., marathon running) or less commonly from single stumbling movements</td>
</tr>
<tr>
<td>Monteggia’s</td>
<td>Fracture of the junction of the proximal and middle thirds of the ulna associated with anterior dislocation of the radial head</td>
<td>Usually caused by fall on outstretched hand along with forced pronation of forearm or by a direct blow on the posterior aspect of the ulna. Reported by Monteggia in 1814</td>
</tr>
<tr>
<td>Nightstick</td>
<td>Fracture of either ulna or radius, or both</td>
<td>Name derived from a citizen’s attempt to protect himself from a police officer’s baton or “nightstick” by offering the forearm</td>
</tr>
<tr>
<td>Piedmont</td>
<td>Closed fracture of the radius at the middle third/distal third junction, without associated ulnar fracture</td>
<td>Named for a series of cases presented at the Piedmont Orthopaedic Society of Durham, North Carolina</td>
</tr>
<tr>
<td>Pott’s</td>
<td>Definitions vary (see comment); most commonly a bimalleolar fracture or a fracture of the distal fibula, 4–7 cm above the lateral malleolus</td>
<td>The exact fracture Pott described in 1769 is uncertain; clearly it referred to a fracture of the lower fibula, usually associated with other fractures or dislocations about the ankle</td>
</tr>
<tr>
<td>Rolando’s</td>
<td>Intra-articular fracture at base of metacarpal. Frequently Y- or T-shaped, or may be severely comminuted</td>
<td>Produced by an axial load with the metacarpal in partial flexion. Worse prognosis than a Bennett’s fracture and, fortunately, rarer</td>
</tr>
<tr>
<td>Salter-Harris</td>
<td>An epiphyseal fracture occurring in children or adolescents</td>
<td>Graded I–V, depending on degree of involvement and/or displacement of epiphysis and metaphysis (see text dealing with Salter-Harris fractures and also Figure 46-1)</td>
</tr>
<tr>
<td>Smith’s</td>
<td>Extra-articular fracture of the distal radius with volar displacement of distal fragment</td>
<td>Reverse of the Colles’ fracture but much more uncommon. Sometimes referred to as a “garden spade” deformity. Usually results from fall with force to back of hand. First described by Smith in 1847</td>
</tr>
<tr>
<td>Stener</td>
<td>Avulsion of the ulnar corner of the base of the proximal phalanx of the thumb</td>
<td>Bony equivalent of rupture of the ulnar collateral ligament, or “gamekeeper’s thumb”</td>
</tr>
<tr>
<td>Teardrop</td>
<td>Wedge-shaped fracture of the anteroinferior portion of the vertebral body; displaced anteriorly</td>
<td>Commonly involves a ligamentous injury and may produce neurologic injury</td>
</tr>
<tr>
<td>Thurston Holland’s fragment</td>
<td>Triangular metaphyseal fragment that accompanies the epiphysis in Salter-Harris type II fractures</td>
<td>Described by Thurston Holland in 1929. The name is commonly hyphenated, although technically it should not be</td>
</tr>
<tr>
<td>Tillaux</td>
<td>Isolated avulsion fracture of the anterolateral aspect of the distal tibial epiphysis</td>
<td>Occurs in older adolescents (12–15 years old) after the medial parts of the epiphyseal plates close, but before the lateral part closes. External rotation force places stress on anterior talofibular ligament. Described by Tillaux in 1872</td>
</tr>

establish a relationship: no study has established the safety, benefit, or accuracy of this maneuver. If doubt exists, an open fracture should be assumed to be present.

The next item that should be noted in the description of a fracture is the exact anatomic location, including the name of the bone, left or right, and standard reference points along the bone, for example, the humeral neck or posterior tibial tubercle.

**Figure 46-1.** Types of fractures.  

Long bones can be divided into thirds—proximal, middle, or distal—and these thirds or the junction of any two of them (e.g., the junction of the middle and distal third of the tibia) are used to describe fractures. The most descriptive language possible should be used. It is better to say “closed fracture of the right ulnar styloid” than “closed fracture of the right distal ulna” because the former conveys more precise anatomic information.

An additional modifier describes the direction of the fracture line in relation to the long axis of the bone in question. A transverse fracture occurs at a right angle to the long axis of the bone (Fig. 46-1A), whereas an oblique fracture runs oblique to the long axis of the bone (Fig. 46-1B). A spiral fracture results from a rotational force and encircles the shaft of a long bone in a spiral fashion (Fig. 46-1C). A fracture with more than two fragments is termed comminuted (Fig. 46-1D).

The position and alignment of the fracture fragments (i.e., their relationship to one another) should be described. Fragments are described relative to their normal position, and any deviation from normal is termed displacement. By convention, the position of the distal fragment is described relative to the proximal one. Displacement may be described as a quantitative measurement (i.e., in millimeters) or as a percentage of the bone width. Figure 46-2 shows a dorsal displacement of the fractured radius, and Figure 46-3 shows lateral, or valgus, displacement of the distal tibia and fibula.

The terms valgus and varus are sometimes confusing. Valgus denotes a deformity in which the described part is angled away from the midline of the body. Conversely, varus denotes a deformity in which the angulation of the part is toward the midline. Alignment refers to the relationship of the longitudinal axis of one fragment to another; deviation from the normal alignment is termed angulation. The direction of angulation is determined by the direction of the apex of an angle formed by the two fracture fragments (Fig. 46-4). This angle is opposite to the direction of displacement of the distal fragment. The relative position or angulation of the distal fragment of a fracture may also be described with terms such as radial or ulnar, dorsal or volar, anterior or posterior, and lateral or medial. One should also be aware of rotational deformity, present when the distal fragment of a fracture is rotated to some degree along the axis of the bone itself. Especially in the hand, radial or ulnar deviation of a flexed finger can occur, and radiographs often underestimate the degree of clinical deformity and rotation present.

**Descriptive Modifiers**

A fracture is termed complete if it interrupts both cortices of the bone and incomplete if it involves only one. It should be noted whether a fracture extends into and involves an articular surface. Frequently the percentage of articular surface involved can only be estimated; in some cases, the percentage that is
actually involved dictates the need to perform a surgical reduction. In general, it is important that the articular surface be restored to anatomic integrity to prevent consequent traumatic arthropathy.

Avulsion fracture refers to a bone fragment that is pulled away from its normal position by either the forceful contraction of a muscle (Fig. 46-5A) or the resistance of a ligament to a force in the opposite direction (Fig. 46-5B). Impaction refers to the forceful collapse of one fragment of bone into or onto another. In the proximal humerus, this collapse typically occurs in a telescoping manner, particularly in elderly patients, whose bones are soft and brittle. In the tibial plateau, impaction occurs frequently in the form of a depression (Fig. 46-6A and B), and in the vertebral bodies, impaction frequently occurs in the form of compression (Fig. 46-6C).

A fracture that occurs through abnormal bone is termed pathologic. A pathologic fracture is suggested whenever a fracture occurs from seemingly trivial trauma. Diseases that cause structural weakness predisposing to injury include primary or metastatic malignancies, cysts, enchondromata, and giant-cell tumors. In addition, osteomalacia, osteogenesis imperfecta, scurvy, rickets, and Paget’s disease all weaken bones, making them susceptible to fracture. The term pathologic also is applied to fractures through osteoporotic bone when the demineralization is a result of disease, as in polio. Fractures through osteoporotic bone of the elderly usually are not described as pathologic. When fractures occur in normal bones and a history of “trivial trauma” is elicited, violence or battering should be suspected. Repeated low-intensity forces may lead to resorp-
tion of normal bone, resulting in a stress fracture. Other names for this condition are fatigue fracture and march fracture (see Table 46-1). Most stress fractures occur in the lower extremities and commonly affect individuals involved in activities such as running, basketball, aerobics, and dancing. Extrinsic factors such as training regimens, type of equipment used, and nutrition habits, as well as intrinsic factors such as anatomic variation, muscle endurance, and hormonal factors have all been associated with stress fractures. These injuries may not be recognizable on initial plain films; therefore, management should be based on clinical diagnosis.\(^1\) The tibia, fibula, metatarsals, navicular, cuneiform, calcaneus, femoral neck, or femoral shaft may be involved.\(^2,3\)

Fracture Eponyms

Many fractures were described before the advent of radiography and are described by an eponym rather than the exact bony injury. These eponyms reflect the rich history of orthopedic care and, despite the objections of some, are still commonly used to describe orthopedic injuries (see Table 46-1).

Fracture Healing

Specific fractures are discussed in subsequent chapters. In general, the goal is to realign bony fragments so that healing or union can take place and normal function is restored. The process from fracture to union begins with a hematoma, caused by rupture of vessels crossing the fracture line. The hematoma bridges the fragments and is followed by an inflammatory phase when granulation tissue forms on the fracture surfaces. Resorption of the hematoma provides the first continuity between the fragments; however, this procallus provides no structural rigidity for bearing stress. With remodeling, callus subsequently is formed on the periosteal and endosteal surfaces of the bone, acting as a biologic splint. This area first becomes mineralized by deposition of calcium phosphate and then undergoes osseous metaplasia. Callus is resorbed as the original fracture surfaces develop firm bony union. In some bones, such as the skull and the neck of the femur, where periosteum is deficient, there may be virtually no callus formation.

Radiographic studies conducted 10 to 14 days after injury show the bone surrounding the fracture line becoming less dense because of localized bone resorption and hyperemia associated with the formation of granulation tissue. As a result, the fracture becomes considerably easier to visualize radiographically about 10 days after injury. After 2 to 3 weeks, soft tissue swelling has regressed, and callus first becomes visible, initially in a mottled pattern and then taking on a dense appearance. The callus undergoes organization, with peripheral margins becoming smooth as physically unstressed portions are resorbed.

For a healthy adult, the whole process from injury to consolidation takes about 2 months for the humerus and about 4 months for a large bone such as the femur. Oblique fractures
tend to heal more quickly than transverse fractures. Healing is quicker in children and slower in the elderly. The rate of fracture healing is affected by many factors, including the type of bone (cancellous bone heals faster than cortical bone); degree of fracture and opposition; and systemic states, such as hyperthyroidism or excess corticosteroidism. Exercise speeds healing, whereas chronic hypoxia has been known to slow repair.

The presence of abundant callus seen on radiograph that is beginning to organize is usually associated with clinical union. If any suggestion of movement at the fracture site is noted on clinical examination, union must be regarded as inadequate. Several terms are used to denote abnormal union. Delayed union is union that takes longer than usual for a particular fracture location. Malunion occurs when a residual deformity exists. Nonunion is the failure of a fracture to unite. When nonunion results in a false joint, it is termed a pseudarthrosis.

If the ends of the bone have remained constant on serial films and an adequate surrounding sheath of organizing callus can be seen, it is permissible for the patient to return to limited active use, even if the original fracture remains visible. The final process of consolidation develops later.

**Fractures in Children**

Certain features of children’s bones distinguish pediatric fractures from adult fractures. Bones of children are necessarily soft and resilient and sustain numerous incomplete fractures. Greenstick fractures are incomplete angulated fractures of long bones. The resultant bowing of the bone causes an appearance resembling a moist, immature branch that breaks in a similar fashion when bent (Fig. 46-7A). A torus fracture is another form of incomplete fracture, characterized by a wrinkling or buckling of the cortex. In Greek architecture, a torus is a bump at the base of a column, and these fractures, occurring at the end of long bones, take on such an appearance. These fractures may be extremely subtle on radiographs (Fig. 46-7B).

Another feature of growing long bones that is a frequent source of trouble and confusion is the presence of epiphyses, cartilaginous centers at or near the ends of bone that give rise to growth of the bone. Figure 46-8 is a schematic review of the anatomy of a growing bone. Because cartilage is radiolucent, the cartilaginous portion of an epiphysis is not visualized on radiographs. A tendency exists to consider only the ossified nucleus and to ignore the cartilaginous structure that bridges to the metaphysis. Cartilage is present even before an ossified nucleus is seen. Because the epiphyseal growth plate is represented by a radiolucent line, confusion may exist as to whether a fracture line is present. These complexities in interpreting radiographs in children sometimes, but not always, require comparison radiographic views of the noninjured side. Injuries to the epiphyses may result from either compressive or shearing forces. These injuries are relatively common during childhood as opposed to sprains or shaft fractures and must be considered in children with a “sprained ankle” because of the relative weakness of the cartilaginous growth zone, which
usually produced by a compressive force. This type of injury may be disrupted. Anatomic reduction does not occur with type I and II injuries.

Type II injuries are similar to type I injuries, with a fracture extending into the metaphysis. The triangular metaphyseal fragment sometimes is referred to as the Thurston Holland sign (see Table 46-1). Type II injuries account for approximately three fourths of all epiphyseal fractures. Because the germinal layer is not involved, growth disturbance usually does not occur with type I and II injuries.

Type III injuries are composed of a slip of the growth plate plus a fracture through the epiphysis, involving the articular surface. Because this fracture involves the germinal layer, growth may be disrupted. Anatomic reduction does not eliminate the possibility of growth disturbance. Type IV fractures are similar to type III fractures, with the additional involvement of a metaphyseal fracture. Anatomic reduction is essential and usually requires surgery. Growth disturbance occurs in a high proportion of patients.

Type V fractures are crush injuries of the epiphyseal plate, usually produced by a compressive force. This type of injury usually occurs in joints that move in one plane, most commonly the knee and ankle. Because this injury occurs in a radiolucent area, the injury may be difficult to diagnose on radiograph, but it is suggested by mechanism of injury and pain over the epiphysis. The diagnosis can be established by MRI if hemorrhage or a hematoma is identified within the growth plate immediately after injury. Also reported is loss of MRI signal from the cartilage. Growth arrest, manifest by shortening or angulation, is the rule in this injury. Type V injuries are extremely rare.

In a study of 410 fractures in children, 16.3% were torus fractures, and 13.9% were epiphyseal injuries. Dislocations and subluxations were rare (3%), and most involved the radial head or the patella. There were no shoulder dislocations. The most common sites were the bones of the distal forearm and the hands (usually the phalanges), each group accounting for 20% of the total. The clavicle was involved 13% of the time; the elbow, 8%; the ankle, foot, and femur, 7% each; and the midforearm, lower leg, and humerus, 4 to 6% each.

Another study found an incidence of epiphyseal injury of 18% in 2000 bony injuries in children. The peak age at the time of injury was 12 years in boys and 11 years in girls. In this series, the incidence of injury by category was type I, 8.5%; type II, 73%; type III, 6.5%; type IV, 12%; and type V, 0.5%. The sole Salter-Harris type V injury in this series occurred in the proximal tibia. The most frequent sites of Salter-Harris type III fractures are the phalanges and distal tibia, and most type IV fractures occur in the distal humerus and distal tibia. The overall frequency of growth arrest in all injuries is 1.4%, whereas the frequency of serious complications is less than 0.6%. The prognosis depends more on the location of the fracture than the Salter-Harris classification. The proximal tibia is the most common site for growth disturbance. Because the epiphysis is closer to fusing, the chances of growth disturbance are less; this influences decision making in terms of surgical versus conservative management.

### Diagnostic Modalities for Fracture Diagnosis

#### Plain Radiography

Plain radiography is the mainstay in diagnosing fractures. In addition to confirming or excluding fractures, other pathologic conditions can be identified. With penetrating trauma, foreign bodies, air, and gas also may be detected. With minor trauma, and when good follow-up monitoring is ensured, it is acceptable to delay radiography. Delay cannot be permitted, however, when the suggested injury is one that might be made worse by delayed diagnosis, such as a nondisplaced hip fracture.

At least two views perpendicular to each other are mandatory in examining long bones, and an oblique view also is usually obtained. In certain locations, such as the phalanges, oblique views are necessary. If doubt still exists, the clinician should ask for more views in various degrees of obliquity to the other films. A fracture line is most visible when it is parallel to the x-ray beam and is invisible when it is exactly 90° to the beam. The clinician should never accept a study that examines the bone in only one plane. When a long bone is found to be fractured, it is imperative that the bone be viewed radiographically in its entire length.

Each film must be examined to ensure that proper technique is used and that no important area is omitted from the film. Overexposed films may fail to reveal an abnormality. Although some fine detail is lost on portable films, these are acceptable in unstable patients, in whom the risk of moving the patient does not outweigh the benefit of the more detailed study. Computed (digital) radiography is now in widespread use. An advantage of this technique is the ability to alter the image-processing parameters based on a specific clinical problem after an exposure has been made. Disadvantages are that the spatial resolution of computed radiographs, and especially of computer monitor formats, is less than that of standard screen-film combinations and that minimization is often necessary when larger body parts, such as the thoracic spine, lumbar spine, and pelvis, are being examined. Despite these considerations, computed radiography seems to be acceptable and does not seem to diminish reader performance significantly.

Even with good technique, some fractures are not visible initially and do not appear until the margins of the fracture absorb. Absorption widens the lucent line, and a defect appears in 7 to 10 days. At that time, new bone produced beneath the periosteum at the margins of the fracture accentuates the fracture. Accordingly, if a fracture is suggested but not visible at the initial visit, the injury should be treated as a fracture and reexamined clinically and radiographically in 7 to 10 days, and the patient should be informed of the rationale for this regimen.

**Stress views** of joints are used in some instances to evaluate the degree of ligamentous injury. Some authors argue against the use of stress views, citing a risk of further injuring an already traumatized structure, additional radiation exposure to the patient and the technologist, and the possibility that pain may not allow sufficient stress to be applied. For these reasons, stress views should be used judiciously in circumstances when other methods of evaluating ligamentous injuries are not available. **Comparison views** are useful in selected situations but should not routinely be performed in all pediatric examinations. If a fracture is definitely present on the affected side, the comparison view exposes the child to radiation and adds expense with no benefit. Similarly, an experienced physician generally is able to read a normal film with reasonable certainty. It is reasonable to use comparison views in instances when radiographs are inconclusive and when the confusion arises specifically out of the need to distinguish between a possible fracture and normal developmental anatomy. Obtaining a wide field of the affected extremity is more useful than routine comparison views for a young child because the child often does not localize the pain well; this is especially true with regard to complaints of knee pain in cases of hip injury or wrist complaints in forearm and elbow injury. Comparison views sometimes are helpful in adults when a question of accessory ossicles or nonfused bones (e.g., bipartite patella) exists because these anomalies are usually bilateral. The bleeding that inevitably accompanies fractures may produce soft tissue swelling, which may impinge on or obliterate overlying muscle planes. Fat pads, such as in the elbow, may be displaced. Another useful sign is the fat-fluid level, which may accompany fractures extending into the knee joint. The fat-fluid level is visible, however, only if the cross-table technique is used.

The bones themselves should be examined systematically. Normal adult bones possess a smooth unbroken contour. A distinct angle is highly suggestive of a fracture. In an adult, the typical fracture is represented by a lucent line that interrupts the smooth contour and usually extends to the opposite side. Nutrient arteries may be confused with fractures, but have different radiographic characteristics: They are fine, sharply margined, extend obliquely through the cortex, and are less radiolucent than fractures. **Pseudofractures** can be created by soft tissue folds, bandages or other overlying material, or a radiographic artifact called the Mach effect. If lucencies extend beyond the bones, the line is highly unlikely to represent a fracture. Anomalous bones and calcified soft tissue likewise may be mistaken for fractures. Avulsions and small fracture fragments have an irregular, uncorticated surface, and a defect in the adjacent bone is present, whereas anomalous ossification centers (accessory ossicles) and sesamoids are characterized by smooth cortical margins. Reference texts are useful in identifying and confirming these anomalies because they tend to occur in predictable locations. Compression fractures are represented by increased density rather than a luency. Finally, the most commonly missed fracture is the second fracture. One must be diligent in searching for additional fractures after discovering the first fracture on a study. In particular, certain paired fractures, such as the distal tibia and proximal fibula, should be sought out.

**Special Imaging Techniques**

**Radionuclide Bone Scanning.** In the past, radionuclide bone scanning was used to detect skeletal abnormalities not radiographically evident in children and adults. Occult lesions, especially stress fractures, acute osteomyelitis, and tumors, can be detected on these scans, although there are problems with specificity and sensitivity. This modality has been largely supplanted by CT and MRI and now is seldom used.

**Computed Tomography.** CT is used to confirm possible fractures or to define better displacement, alignment, or fragmentation of fractures. It also is useful in trauma to rule out cervical spine fracture when plain films are equivocal and in noncompressive vertebral fractures to assess the number of fragments and their spatial relationship to the spinal canal. CT is used frequently to define the integrity of articular surfaces in the acetabulum, knee, wrist, or ankle and in Salter-Harris type IV fractures.

**Magnetic Resonance Imaging.** MRI constitutes the most advanced noninvasive examination of orthopedic structures, delineating lesions of bone, cartilage, ligaments, and other structures, such as menisci, disks, and epiphyseal structures. MRI is expensive and time-consuming and should be reserved for instances when the diagnosis is in doubt and specific findings would alter the treatment.

**Complications of Fractures**

**Infection (Osteomyelitis)**

Any fracture communicating with the surface of the skin is termed an open fracture. Open fractures are treated as true orthopedic emergencies because of the risk of infection; the dreadful nature of the complication of osteomyelitis dictates that no time should be wasted in initiating therapy (Box 46-2). Wounds should be covered with sterile dressings, and paren-
teral antibiotics should be instituted as early as possible. Currently, suggested therapy includes a first-generation cephalosporin, such as cefazolin, for all open fractures, with the addition of an aminoglycoside for grade II or III fractures.\textsuperscript{13,14} Although the traditional recommendation has been to obtain culture and sensitivity before starting antibiotics, the usefulness of this approach has not been supported by a controlled study.\textsuperscript{13} A retrospective analysis of perioperative cultures in open fractures in children failed to show any value in predicting the identity of subsequent infecting pathogens.\textsuperscript{16} It is prudent to omit such cultures.

Certain open fractures of the finger present a notable exception to the previous recommendation. Such injuries, especially an open distal tuft fracture, are common when the phalanx of a finger is subject to crush injury (e.g., by a door), and there exists a skin defect overlying a fractured bone. In a prospective randomized, placebo-controlled study of 193 patients with open fracture of the finger, fluclloxacillin or placebo was administered to randomized patients with open phalangeal fractures, and both groups were treated with aggressive surgical irrigation and débridement. No significant difference was found in the infection rate between the groups, and no patient developed osteomyelitis. The data suggest that vigorous irrigation and débridement are adequate primary treatment for open phalangeal fractures in fingers with intact digital arteries.\textsuperscript{17} Such injuries might be repaired by the emergency physician without consultation.

### Hemorrhage

Because of the rich blood supply to the skeleton, fractures can result in large amounts of blood loss, shock, and death from exsanguination. In particular, certain pelvic fractures can cause great blood loss because adequate tamponade is not possible. In adults, blood loss can range from 100 mL from a forearm fracture to 3 L from a pelvis fracture (Table 46-3).

### Vascular Injuries

Vascular injuries characteristically are associated with certain fractures. Fractures and dislocations about the knee result from tremendous force that often injures the popliteal artery. In the extremities, assessment of vascular injuries may be difficult. The initial survey should note the presence or absence of pulses and the state of capillary filling. If an end artery is completely disrupted, the tissue distal to the injury may exhibit the classic five P’s: pain, pallor, pulselessness, paresthesias, and paralysis. Incomplete and subclinical injuries occasionally occur, however, that initially may be asymptomatic and nondetectable. Likewise, in an unconscious, multiply injured patient, major vascular injuries may not be obvious. The mechanism of injury and anatomy dictate the need to assess the possibility of an injured vessel. If pulses cannot be palpated, a Doppler stethoscope should be used to listen for blood flow. Even palpable pulses may be misleading, however, because it has been shown that in 10 to 20% of significant arterial injuries, distal pulses may initially be normal. When pulses are present, but the mechanism of injury suggests the possibility of vascular injury, additional diagnostic studies or surgical exploration may be necessary. Late complications of undiagnosed vascular injuries include thrombosis, arteriovenous fistulae, aneurysm, false aneurysm, and tissue ischemia with limb dysfunction.

Traditionally, conventional arteriography has been the diagnostic modality of choice in evaluating vascular injuries; however, it is invasive and costly. Alternative methods of vascular assessment include arterial pressure indices and serial physical examinations. Recent advances in computed tomographic angiography have proven it an effective alternative to conventional arteriography, and its advantages include immediate availability and noninvasiveness.\textsuperscript{18}  

#### Nerve Injuries

Nerves can be injured by either blunt or penetrating trauma. 

**Neurapraxia** is the contusion of a nerve, with disruption of the ability to transmit impulses. Paralysis, if present, is transient, and sensory loss is slight. Normal function usually returns to a neurapraxic nerve in weeks to months. **Axonotmesis** is a more severe crush injury to a nerve. The injury to nerve fibers occurs within their sheaths. Because the Schwann tubes remain in continuity, spontaneous healing is possible but slow. **Neurotmesis** is the severing of a nerve, usually requiring surgical repair. Age, site, injured nerve, and delay between injury and repair have all been shown to influence prognosis after microsurgical repair.\textsuperscript{19} Because of proximity, specific nerve injuries characteristically accompany certain fractures (Table 46-4).

When the nerve is completely severed, all functions are absent, including superficial sensation to touch, pain, and temperature; deep sensation to muscle and joint movements, position, deep pressure, and vibration; motor supply and deep tendon reflexes (to distally innervated muscle groups); and response to electrical stimulation. For less severe injuries, any subjective change in sensation should be noted. Light touch is a good screening test. Two-point discrimination is a more sensitive examination and should be used routinely in evaluating digital nerves. Separating the ends of a paper clip and asking the patient to discriminate between one or two points may easily accomplish this. Two-point discrimination may be of limited value in children in whom a subjective response may be misleading; this is also true in patients with calloused fingertips and in patients who are uncooperative, comatose, in severe pain, or intoxicated. Testing for sympathetic nerve function using the O’Riain wrinkle test may be helpful.\textsuperscript{20} Soaking the normally innervated digits in warm saline for 20

**Table 46-4 Nerve Injuries Accompanying Orthopedic Injuries**
Compartment Syndrome

Compartment syndrome is a serious acute emergency complication that should be considered whenever pain and paresthesias occur in an extremity after a fracture within an enclosed osseofascial space (Table 46-5). The immediate threat is to the viability of nerve and muscle tissue within the involved compartment, but infection, gangrene, myoglobinuria, and renal failure also may ensue. Compartment syndrome is associated most commonly with a closed long bone fracture of the tibia, but it also is well described in the thigh, forearm, arm, hand, and foot.21-25 In addition, compartment syndrome can occur with soft tissue trauma alone and even with open fractures. It also has been described in a host of unusual situations, including prolonged procedures in the lithotomy position, the tuck position (knees tucked to the chest for lumbar surgery), coma, spontaneous hemorrhage, intravenous injections, and the application of excessive traction in treatment of a fracture.26-28

Pathophysiology. Increased pressure in a closed nonexpandable compartment essentially represents a mismatch between the volume of that space and its contents. As such, it may arise from one of three circumstances: (1) increased compartment contents, (2) decreased compartment volume, or (3) external pressure (Box 46-3). As tissue pressure increases, so does venous pressure, resulting in compromise of the local circulation and tissue hypoxia; this is believed to occur at pressures that are above normal diastolic pressure but below systemic arterial pressure because of a reduced arteriovenous gradient at the tissue level. The body responds by releasing histamine in an attempt to dilate capillaries and increase blood flow to the affected area. Histamine also increases capillary membrane permeability, resulting in a leak of proteins and fluid into the surrounding tissue, further increasing compartment pressure.

As tissue pressure continues to increase, venous blood flow is impaired as capillary perfusion pressure is exceeded. Finally, arterial capillary blood flow falls to a point where the basic metabolic needs are no longer met, leading to ischemic necrosis of muscles and nerves within the compartment. An important concept in the management of compartment syndrome is that because local venous pressure cannot be significantly below local tissue pressure, and because elevation of a dependent limb decreases local arterial pressure by 0.8 mm Hg for each 1 cm of limb elevation, elevation of a limb with resultant reduction in the local arteriovenous gradient may be counterproductive and may exacerbate compartment syndrome. Vascular spasm seems to play an insignificant or minimal role in the development of compartment syndrome, as evidenced angiographically, where spasm has never been shown, and clinically, where it is observed that distal pulses usually are maintained until late in the course.

Normal compartment pressure is 0 mm Hg. Microcirculation generally is impaired when tissue pressures reach 30 mm Hg or more; however, some patients can tolerate much higher
compartment pressures without compartment syndrome developing. Controversy exists over attempts to define compartment syndromes on the basis of specific tissue pressure. The tolerance to tissue ischemia varies among individuals because of shock, compensatory hypertension, altered tone in resistance vessels, and other unknown factors. Inadequate perfusion and relative ischemia begin when tissue pressure within a closed compartment increases to within 20 mm Hg of a patient’s diastolic pressure or, more accurately, within 30 mm Hg of the mean arterial pressure. When tissue pressure equals or exceeds the patient’s diastolic pressure, tissue perfusion effectively ceases. The development of muscle ischemia depends not only on the magnitude but also on the duration of elevated pressure. Intracompartmental pressures do not measure muscle and nerve ischemia but rather suggest the existence of the proper setting for compartment syndrome.

**Anatomic Considerations and Risk Factors.** Compartment syndrome theoretically can develop in any location where neuromuscular tissue is contained in a limiting envelope. The condition has been reported in the leg, thigh, buttock, arm, forearm, and hand (Box 46-4). By virtue of its location and higher likelihood of sustaining high-energy trauma, the leg, particularly the anterior compartment, is most commonly involved.

In a study of 164 patients treated over an 8-year period in the United Kingdom, a fracture was present in 69%, and half of these involved the tibial shaft. Perhaps more significant is that 31% of patients had only soft tissue injury without fracture. Most patients were men younger than age 35. Ten percent of patients either had a bleeding disorder or were taking anticoagulants. Traffic accidents and sports activities were the most common mechanisms of injury.

**Clinical Presentation.** In a conscious and fully oriented patient, pain that is disproportionate to the injury or physical findings is a hallmark finding in compartment syndrome. Pain often is characterized as deep, burning, and unrelenting and is difficult to localize. The need for increasing amounts of analgesics should not lead the clinician automatically to the conclusion that the patient is drug-seeking; rather, it should serve as a prompt to the possibility that a compartment syndrome is developing or is present.

Pain on passive stretching of the muscle groups in the suggestive compartment is an important finding. In addition, active flexion of involved muscles may produce pain. Other reliable suggestive signs and symptoms are hypoesthesias and paresthesias in the distribution of nerves crossing the compartment or tenderness, tenseness, or the sensation of tightness of the compartment.

Skin color, temperature, capillary refill, and distal pulses all are unreliable monitors for compartment syndrome because the pressure necessary to produce compartment syndrome is well below arterial pressure. Pallor and loss of pulses are late and ominous signs. Diminished pulses should suggest concomitant pathologic conditions responsible for reduced arterial flow. Although it is still frequently taught that the five P’s (pain, pallor, pulselessness, paresthesias, and paralysis) are signs and symptoms of compartment syndrome, this is generally not true. Rather they are the signs of acute disruption of arterial flow. Subjective complaints are an important indicator of compartment syndrome. Patients who are not fully alert or cooperative must be assessed with particular care.

**Diagnostic Tests.** If the history and examination suggest compartment syndrome, compartment pressures should be measured using any of the commercially available monitors (Fig. 46-9). The two most common methods of determining compartment pressures are the slit-catheter techniques and the side-port needle. The Stryker device is a hand-held digital display that is easy to use with minimal training. Care must be taken to zero the monitor in on the plane in which it will be inserted to account for the effects of gravity. It is also paramount that the appropriate compartment is measured. Pressures of less than 30 mm Hg generally do not produce compartment syndrome. Pressures exceeding 30 mm Hg or within 30 mm Hg of the patient’s mean arterial pressure are an indication for fasciotomy. Serial or continuous pressure measurements should be performed in cases that are not clear-cut. Compartment syndrome can occur at pressures significantly below systemic pressure. Doppler ultrasound is not useful in evaluating these patients because excellent arterial blood flow may be documented even in the presence of raised intracompartmental pressures.

**Figure 46-9.** A. Hand-held device for measuring compartment pressure. B. Insert device perpendicular to skin.
of a significant compartment syndrome. Newer devices based on near-infrared spectroscopy (NIRS) measurement of tissue oxygenation have proven effective experimentally in detecting compartment syndrome but will require validation in the clinical setting before widespread application.\textsuperscript{31}

**Treatment, Complications, and Disposition.** Complete fasciotomy is the only treatment that can reliably normalize elevated compartment pressure. Preparation for surgery must be done as quickly as possible. Delaying fasciotomy for more than 12 hours often results in irreversible muscle and nerve damage. While the patient is awaiting definitive treatment, the affected part should not be elevated above the level of the heart because this maneuver does not improve venous outflow and reduces arterial inflow. Slight dependency has been suggested to maximize the pressure head in the extremity.

Rhabdomyolysis, hyperkalemia, and myoglobinuria may occur and should be managed aggressively to avoid renal failure. Lactic acid also is released from necrotic muscle tissue. Other complications include infection and tissue loss. Delayed treatment results in loss of nerve and muscle function and eventual contracture formation. The magnitude of these disasters may be measured by the fact that in 2004, the average indemnity award in cases of missed compartment syndrome was nearly $426,000. Awards were proportional to the delay beyond 8 hours in performing fasciotomy and the number of the “five P’s” indicating ischemia that were present during the initial missed diagnosis.\textsuperscript{32} For these reasons, when the diagnosis of compartment syndrome is confirmed, fasciotomy should be done without delay.

**Avascular Necrosis**

Because of their blood supply, certain bones may undergo avascular necrosis after fracture, especially if fractures are comminuted and go untreated for any length of time. The femoral head, talus, scaphoid, lunate, and capitate are particularly prone to this complication.\textsuperscript{33,36}

**Complex Regional Pain Syndromes (Reflex Sympathetic Dystrophy and Causalgia)**

**Definitions.** The terms reflex sympathetic dystrophy (RSD) and causalgia have been used to describe pain syndromes that sometimes follow fractures, orthopedic surgery, soft tissue injuries, and other unrecognized trauma to the limbs and their appendages. Other names previously used for this spectrum of posttraumatic injuries include Sudeck’s atrophy, shoulder-hand syndrome, and postinfarction sclerodactyly. In an attempt to reduce misunderstanding about their etiology and treatment, the International Association for the Study of Pain issued a consensus statement renaming the syndromes formerly called RSD and causalgia.\textsuperscript{37,38} Complex regional pain syndrome type I (CRPS-I), replacing the term RSD, is a pain syndrome that develops after an initiating noxious event, extends beyond the distribution of a single peripheral nerve, and is usually disproportionate to the inciting event. The site is most often the distal end of the affected extremity, with a distal-to-proximal gradient. It is associated with edema, changes in blood flow to the skin, abnormal sudomotor activity in the region of the pain, allodynia (pain resulting from non-noxious stimulation to the skin), hyperpathia (pain persisting or increasing after mild or light pressure), or hyperalgia. The presence of a condition that otherwise would explain the degree of pain and dysfunction excludes the diagnosis of CRPS-I. Because so much of the literature still refers to RSD, this chapter still uses the terms RSD and CRPS-I interchangeably. The definition of CRPS-II is the same as for CRPS-I except that there is demonstrable peripheral nerve injury. This term replaces causalgia under the International Association for the Study of Pain taxonomy.

**Pathogenesis and Etiology.** The pathogenesis of CRPS-I has not been elucidated. The sympathetic nervous system seems to play a role in the maintenance of the symptoms in some, but not all, patients. Cases of CRPS-I have been reported after fractures and as iatrogenic complications of surgery or after minor procedures, including subcutaneous excision and intravenous injection. Forceful manipulations and tight casts also are alleged to have produced the syndrome. In 10 to 26% of patients, no inciting event is identified.\textsuperscript{39,40}

Although malingering and secondary gain are suspected in some patients, they are not the causes in most patients, as evidenced by pathologic tissue changes in patients who actually have CRPS-I.\textsuperscript{41} CRPS-I occurs in children and adolescents.\textsuperscript{42} Girls are affected three times as often as boys, and the median age is 12 years. The lower limb is affected twice as often as the upper, and history of inciting trauma can be identified in only half the children with the disorder.

**Diagnosis.** No correlation exists between the severity of the original trauma and the incidence, severity, and cause of the symptoms, making early diagnosis a challenge, especially after trivial injury. Early diagnosis is crucial because the earlier treatment is initiated, the better the response. The diagnosis is not always easy to make, however.

An RSD score consisting of nine criteria has been proposed to aid in the diagnosis of RSD and to enhance comparisons of outcome studies.\textsuperscript{43} The criteria are as follows:

1. Alloodynia (pain resulting from non-noxious stimulation to the skin) or hyperpathia (pain persisting or increasing after mild or light pressure)
2. Burning pain
3. Edema
4. Color or hair growth changes
5. Sweating changes
6. Temperature changes
7. Radiographic changes (i.e., demineralization)
8. Quantitative measurement of vasomotor/sudomotor disturbance
9. Triple-phase bone scan consistent with RSD

One point is given for each positive criterion, none if absent, and half a point if equivocal. Patients with more than five points are probable RSD patients. Pain that is abolished with temporary selective sympathetic blockade is another test that is highly suggestive of RSD.

**Treatment.** Treatment of CRPS is controversial. Debate arises because randomized, placebo-controlled studies are lacking; individual response to treatment varies; and experts disagree regarding the pathogenesis of the disease. A multidisciplinary approach, including physical therapy and psychological counseling, is often necessary to treat CRPS.\textsuperscript{44} For some patients, definitive treatment involves sympathetic blockade, usually with regional anesthesia and occasionally by surgical sympathectomy.\textsuperscript{45} Oral medications, including biphosphonates, calcitonin, indomethacin, corticosteroids, tricyclic antidepressants, gabapentin, acupuncture, spinal cord stimulation, regional nerve blocks, and others, have been used to treat RSD with variable success.\textsuperscript{39,46} In one study, vitamin C was shown to reduce the incidence of RSD after wrist fracture.\textsuperscript{47}

**Fat Embolism Syndrome**

Fat embolism refers to the presence of fat globules in the lung parenchyma and peripheral circulation after a long bone frac-
The phenomenon of fat embolization is probably common as a subclinical event after long bone fracture. Intravascular fat droplets appear in nearly one of five patients admitted with major trauma, although not all patients are symptomatic or require treatment.

Fat embolism syndrome is a serious manifestation of fat embolism, occurring most commonly after long bone fractures (usually tibia and fibula) in young adults and after hip fractures in elderly patients. Symptoms usually appear 1 to 2 days after an acute injury or after intramedullary nailing. Respiratory distress and hypoxemia are the earliest, most common manifestations. Acute respiratory distress syndrome (ARDS) may occur and is the usual cause of death. Neurologic involvement, manifesting as restlessness, confusion, or deteriorating mental status, also is an early sign, as are thrombocytopenia and a petechial rash. Fever, tachycardia, jaundice, retinal changes, and renal involvement may occur. Fat is seen in the urine in 50% of patients within 3 days of the injury. The incidence of full-blown fat embolism syndrome varies from 0.5 to 2% in patients with isolated long bone fractures to 5 to 10% in patients with multiple fractures. Management of fat embolism syndrome is primarily supportive, usually in an intensive care unit. The mortality rate is 20%, but most patients recover without severe sequelae. No specific therapy has shown benefit.

- Deep venous thrombosis
- Pulmonary embolism
- Urinary tract infection
- Wound infection
- Decubitus ulcers
- Muscle atrophy
- Stress ulcers

**Fracture Blisters**

Fracture blisters are tense blisters or bullae that accompany high-energy injuries in areas of relatively little skin coverage over a fracture site. The ankle, elbow, foot, and knee (in that order) are the most common sites; all of these contain fewer hair follicles and sweat glands to anchor together the epidermal-dermal junction than do other limb locations. Fracture blisters are believed, in many cases, to occur in the setting of increased underlying tissue pressure and may be a harbinger of compartment syndrome.

Early surgical intervention reduces the incidence of fracture blister formation. In addition, the presence of a fracture blister requires an alteration of the surgical approach or a delay in surgery. Most experts discourage incisions through a fracture site because such incisions seem to increase infection and skin breakdown. Measures to perform early surgery after high-energy injuries and to minimize increases in tissue pressures might reduce the incidence of this complication. Intact blisters should be covered with povidone-iodine solution and a sterile dressing. Unroofing the blister and applying coverage with silver sulfadiazine paste has been reported to decrease the incidence of complications.

**Complications of Immobilization**

Fractures frequently result in long periods of immobilization. Immobility may lead to multiple medical problems, especially in elderly patients, including pneumonia, deep venous thrombophlebitis, pulmonary embolism, urinary tract infection, wound infection, decubitus ulcers, muscle atrophy, stress ulcers, gastrointestinal hemorrhage, and psychiatric disorders (Box 46-5). Early ambulation is a major goal of optimal orthopedic care.

**SUBLUXATION AND DISLOCATIONS**

**Nomenclature**

Abnormal forces applied to joints may result in the loss of continuity between two articulating surfaces. Partial loss of continuity is termed *subluxation*, and complete loss is termed *dislocation*. In general, dislocations are named for the major joint involved, as in a dislocated shoulder or hip. In three-bone joints, the injury is named for the joint involved if the disturbance involves the two major bones, or, if the lesser bone is involved, the disturbance is named for that bone. Separation of the femur from the tibia is termed *dislocation of the knee*, whereas displacement of the patella from its normal articulation is termed *dislocation of the patella* (Fig. 46-10). At the elbow, separation of the olecranon from the humerus is a *dislocation of the elbow*, whereas separation of the radius from the humerus is termed *radial head dislocation*.

Dislocations and subluxations should be described according to the direction of the distal segment relative to the proximal segment or of the displaced bone relative to the normal structures. The injury shown in Figure 46-11 is termed *dorsal dislocation of the interphalangeal joint of the thumb*. Disruption of articulation also may occur in combination with a fracture. The term *fracture-dislocation* is used to describe this combination. If the overlying skin is broken in any way, dislocations, subluxations, or fracture-dislocations are described as open and constitute the same emergency as does an open fracture alone.
Assessment

In most cases of dislocation, severe to excruciating pain exists because the joint capsule is stretched or torn. Movement of the joint exacerbates the pain. This useful sign is lost in an obtunded, intoxicated, or unconscious patient and may result in a missed diagnosis if a careful survey is not performed. Some dislocations, such as anterior shoulder dislocation, have an obvious deformity, whereas others, such as posterior shoulder dislocation, may be subtle. Swelling of soft tissues also may obscure the diagnosis, such as in the tarsal-metatarsal region. Gentle passive testing of range of motion should be performed but never forced. Assessment for neurovascular function is similar to that for fracture. Certain dislocations (e.g., knee) are so commonly associated with vascular injuries that a careful assessment of blood flow is important in evaluating these injuries.

Plain radiographic studies detect most dislocations, provided that the correct views are ordered. Radiographs should be performed before and after attempts at reduction at first-time or complicated dislocations, unless there is neurovascular compromise. This confirms the diagnosis and ensures that associated fractures are documented before treatment is undertaken.

Treatment

Methods of relocating specific joints are reviewed in subsequent chapters, but a few general principles apply. In general, the sooner a joint is relocated, the better. Later, swelling and muscle spasm make reduction more difficult. Also, pain is not adequately relieved until the dislocation is reduced. In the hip, early reduction is mandatory to restore vascular supply and to avert the complication of avascular necrosis. Before attempting relocation, adequate analgesia or conscious sedation should be used. Nerve blocks are especially useful on the digits. The general principle of reducing a dislocation is to re-create and reverse the mechanism of injury, pulling the proximal end of the dislocated bone out and away from whatever is trapping it in its final resting place. As this maneuver is accomplished, the disarticulated surface is manipulated back or may snap back spontaneously toward its normal anatomic position. If the reduction is difficult, it should not be forced. A single good attempt is better than repeated attempts in an inadequately relaxed patient. Some joints cannot be reduced in the ED because (1) the opposing muscles are contracting too forcefully and general anesthesia is necessary to overcome these forces or (2) mechanical obstruction by a bony fragment or a torn piece of cartilage, tendon, joint capsule, or skin requires surgical removal for reduction to occur.31

■ SOFT TISSUE INJURIES

Sprains

Nomenclature

Ligamentous injuries resulting from an abnormal motion of a joint are termed sprains. A sprain is defined as injury to the fibers of a supporting ligament of a joint. Sprains may be graded according to the severity of pathologic findings; clinically, however, the grades are often indistinct. First-degree sprains are characterized by minor tearing of ligamentous fibers with resultant mild hemorrhage and swelling. Minimal point tenderness can be elicited. Stressing the ligament produces some pain, but there is no opening or abnormal joint motion.

A second-degree sprain is a partial tear of a ligament, meaning more fibers are torn than in the first-degree injury. Clinical findings include moderate hemorrhage and swelling, tenderness, painful motion, abnormal motion, and loss of function. There may be a tendency toward persistent instability and recurrence, and prevention of these complications is a major goal of treatment.

A third-degree sprain describes the complete tearing of a ligament. Signs include a further exaggeration of the signs mentioned for second-degree sprain. In addition, stressing the joint reveals grossly abnormal joint motion, provided that this is not limited by pain or swelling. Analgesia and the evacuation of a hemarthrosis may be used to allow a more complete diagnosis of these injuries. Chronic joint instability is the rule if severe ligamentous injuries do not heal properly.

Assessment

The clinical presentation of a sprain of the extremity may be indistinguishable from that of a fracture. The injury frequently occurs during vigorous athletic activity when forces applied in opposite directions result in a joint being stressed in an abnormal or exaggerated direction. The patient may complain of hearing a “snap” or a “pop” at the moment of injury and conclude that a fracture must be present. Other patients report “seeing stars” or “almost passing out” at the moment the injury occurred and may still be in extreme pain, appearing pale and diaphoretic if seen shortly after the injury. Analgesia should be provided to these patients. Evaluation should include a careful history of the exact sequence of events at the time of the injury and ascertaining the position of the extremity and the forces applied to it at that moment. A history of any sounds that accompanied the injury should be elicited. Examination of the joint should include stressing it to show abnormal motion. If radiographs are planned to rule out a fracture anyway or if exquisite pain is produced by mild attempts to apply stress, it is probably better to delay stressing until films have verified the absence of a significant fracture. Plain radiography is indicated in some, but not all, cases to rule out a fracture anyway or if exquisite pain is produced by mild attempts to apply stress, it is probably better to delay stressing until films have verified the absence of a significant fracture. Plain radiography is indicated in some, but not all, cases to rule out a fracture. It has been well demonstrated that clinical decision rules can reduce the number of radiographic studies without missing significant fractures.52-53

Avulsion fractures may occur concomitantly with sprains. In children, epiphyseal fractures occur more commonly than ligamentous disruption because of the relative ligamentous strength compared with the ease of disrupting the epiphyses. Arthroscopy or MRI is indicated in the follow-up evaluation of some of these injuries (e.g., for suspected cruciate tears) when significant pain or disability is present.36-38
Specific management of sprains varies depending on the location and severity of the injury. In general, initial measures should include the traditional recommendations of ice, elevation, and analgesia. Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective analgesics in many patients. Several studies have found more rapid decrease in swelling, increased exercise endurance, and earlier return to work with use of NSAIDs.59

Immobilization is used to provide protection and comfort in the initial management of most injuries, using one of the following methods. Because the severity of injury is sometimes difficult to establish at the first visit, it is reasonable to immobilize the affected joint for the first 48 to 72 hours, after which the extent of injury can be better determined. At that time, early mobilization is often desirable, particularly in lateral ankle injuries because this leads to earlier return to work and athletic activities and better preservation of proprioceptive neuromuscular function.60 Use of an inflatable “air cast” alone or in conjunction with an elastic ankle wrap has been shown to be effective in decreasing the symptomatic period.61 For lower extremity injuries, protected weightbearing with crutches provides patients with comfort and avoids motion of the impaired part. In elderly patients, safe ambulation sometimes cannot be accomplished, and a short hospitalization or admission to a skilled nursing facility may be necessary.

For complete or nearly complete ligamentous disruption, urgent orthopedic consultation is usually mandatory. Less severe injuries can be followed up 3 to 7 days postinjury when acute swelling has subsided. Copies of plain films ordered in the ED should be sent with the patient if possible. Physical therapy and rehabilitative exercises sometimes are begun at these visits and carried on for several weeks. Because ligaments are relatively avascular, healing is slow, and patients with significant sprains should be informed of this. Sprains should be diagnosed as precisely as possible and should not be trivialized. Too often, after radiographs have ruled out fracture of an affected extremity, the term sprain is applied indiscriminately, or the patient is told that the injury is only a sprain, a misleading expression that should be avoided. Aside from creating false expectations regarding recovery, thoughtless mislabeling of injuries not in evidence may lead to missed occult fractures in adults or epiphyseal injuries in children.

Strains

Nomenclature

A strain is an injury to a musculotendinous unit resulting from violent contraction or excessive forcible stretch. The term pulled muscle sometimes is used interchangeably with muscle strain. These injuries are graded in a manner similar to sprains.

A first-degree strain is a minor tearing of the musculotendinous unit, characterized by swelling, local tenderness, and minor loss of function. Findings increase along a continuum such that in a second-degree strain, more fibers are torn, but without complete disruption; swelling, ecchymosis, and loss of strength are more marked. In a third-degree strain, the muscle or tendon is completely disrupted, with resultant separation of muscle from muscle, muscle from tendon, or tendon from bone. An accompanying avulsion fracture may be present on radiographs in either second- or third-degree injuries.

Assessment

Signs and symptoms include pain, ecchymosis, swelling, and loss of function. A force applied to the muscle, either passive stress or active contraction, produces sharp pain at the site of injury even as the injured muscle may be relatively comfortable at rest. A palpable defect sometimes is present at the site of a complete rupture, which usually involves the region of the muscle tendon junction, or a bunching up of the muscle may be appreciated. Ultrasound is increasingly being used to diagnose an assortment of soft tissue injuries including rotator cuff tears, tendon ruptures, and muscle tears.62,63 Among nonathletes, strains commonly are seen in patients who have either overstressed a muscle group or tried to generate excessive force in a unconditioned muscle. Examples are the weekend gardener or mover who presents on Monday morning with lower back strain, the aerobics student who strains the rectus muscles, and the weightlifter who presents with chest wall pain resulting from pectoralis major strain. These are usually first-degree injuries, and the onset is slow. Rapid acceleration (e.g., in a tennis player) may result in a third-degree gastrocnemius or plantaris tear, whereas pushing off to jump is a common cause of ruptures of the Achilles tendon in a basketball player. A sudden violent attempt at lifting in an older individual can result in a complete biceps brachii disruption. Sudden generation of forces of which the thighs are capable results in second-degree strain of the hamstrings, quadriceps, or thigh abductor muscles.

In athletes, generation of tremendous contraction forces coupled with excessive forcible stretching (while the body may be either accelerating or “planting”) results in severe strains. Involvement of almost any muscle group is possible, and the onset of such injuries is usually acute. Immediate removal from activity, application of ice, and rest of the affected limb for 48 to 72 hours usually are advised to prevent further injury. A competitive athlete usually is unable to continue anyway because of the accompanying loss of function. After a brief rest period, however, early mobilization and rehabilitation should be encouraged.

Treatment and Disposition

Treatment depends on the degree of disruption, location, and functional loss. Most first-degree injuries respond in a few days to rest, application of ice, and, for some patients, analgesics. NSAIDs commonly are recommended and prescribed, although their efficacy for other than analgesic purposes is unproven. Second-degree strains are treated similarly, with protection against aggravating activity required for longer periods. Third-degree strains receive similar initial treatment in the ED plus early orthopedic consultation. Some of these injuries are amenable to surgical repair, whereas others may be treated with immobilization. The muscle affected and the age, occupation, and activity level of the patient all are factors in deciding whether surgical intervention is appropriate. Many athletes and their trainers believe and it is universally espoused that many strains can be prevented by proper training, warm-up, stretching exercises, and avoidance of overexertion, although limited scientific data exist to support these recommendations.64,65

Tendinitis and Tendinosis

Tendinitis is classically described as an inflammatory condition characterized by pain at tendinous insertions into bone, occurring in the setting of overuse.66,67 It is now believed that the pathophysiology of this condition is more complex than
m ere overuse, with the roles of load and use affecting cell-
matrix interaction. Etiologic factors are believed to include aging, with decreased blood supply and decreased tensile strength; muscle weakness and imbalance; insufficient flexibility; male gender; obesity (in weight-bearing joints); smoking; malalignments; training errors; and improper equipment. Additionally, certain systemic diseases, including diabetes mellitus, chronic renal failure, rheumatoid arthritis, and systemic lupus erythematosus; steroid use; and occasionally fluoroquinolone use are associated with the development of tendinopathy.

With chronicity, involved tissues are characterized morphologically by signs of chronic rather than acute inflammation (infiltration by macrophages, plasma cells, and lymphocytes rather than leukocytes) and degeneration (cell atrophy). It also has been shown that prostaglandin E₂ levels are normal. This evolving understanding of tendinitis in the future should allow for more logical treatment of these injuries aimed at the underlying pathophysiology. It also has led some authors to propose that chronic painful conditions of the tendon should be referred to as tendinosis rather than tendinitis or other terms previously used to describe this condition, including tendonitis, degenerative changes, chronic tendinopathy, or partial rupture. Common sites for tendinitis are the rotator cuff of the shoulder, the Achilles tendon, the radial aspect of the wrist (de Quervain’s tenosynovitis), and the insertion of the hand extensors on the lateral humeral epicondyle (tennis elbow). Also commonly involved in athletes are the patellar tendon, particularly in athletes engaged in jumping sports; the biceps femoris, semitendinosus, and semimembranosus (hamstring syndrome); posterior tibial tendon (shin splint syndrome); the iliobibial band; and the common wrist flexors (medial epicondylitis) seen in little league pitchers and golfers. In some locations, most commonly the shoulder, calcium deposition occurs along the course of the tendon, resulting in a painful condition termed calcific tendinitis. This condition also may occur in the wrist, hand, neck, hip, knee, ankle, or foot.

Physical examination reveals pain with motion and limitation of function and may include point tenderness and palpable crepitus over the involved tendon with motion. In general, a clinical test can be performed by forcible flexion of the involved muscle while keeping the point of insertion fixed or by operating the involved muscle against resistance. Either test should intensify the discomfort. Radiographs are usually negative. A small fleck of bone may suggest an avulsion, or the surface of the bone at the attachment may be roughened, indicating periostitis. As mentioned, there also may be calcium deposits along the course of the tendon, which should not be confused with an avulsion fracture. Ultrasound is sometimes useful in confirming the diagnosis of tendinitis. Although a normal tendon is characterized by a relatively homogeneous pattern, tendinosis is characterized by one or more of the following features: loss of the fibrillar echotexture, focal tendon thickening, diffuse thickening, focal hypoechoic area, irregular or ill-defined borders, or microruptures.

There is little evidence to support any specific treatment for tendinosis. The classic approach consists of rest, ice, and NSAIDs initially, followed by rehabilitation and training and control of force loads to prevent recurrences. Although NSAIDs may be useful for a brief period at the onset of symptoms for their analgesic effects, no evidence exists that they significantly alter the pathophysiology of this condition, and no rationale exists for ordering them in patients at any risk for complications from this class of drugs. Peritendinous local infiltrations of anesthetics and corticosteroids may be useful but should not be repeated too often because tendon rupture may occur. Injection therapy is especially useful in calcific tendinitis around the shoulder. Injection of steroids directly into the Achilles tendon should be avoided because of reports of partial or complete rupture after even a single injection. Some cases of calcific tendinitis that do not respond to conservative therapy may require either arthroscopic or open surgery.

Bursitis

Bursitis is a painful inflammation of the bursa that may be traumatic, infectious, or related to systemic illness. Commonly involved sites include the olecranon, the greater trochanter of the femur, and the prepatellar and anserine bursae around the knee. Physical findings are tenderness and swelling over the involved bursa, whereas warmth and overlying erythema may signal infection. If infection is suggested, aspiration of the bursal fluid and Gram’s staining and culture are recommended. Otherwise, treatment may be conservative and is similar to treatment for tendinitis, with ice, NSAIDs, or steroid injections. Most patients can be treated as outpatients.

TREATMENT MODALITIES

Splinting and Bandaging

Suggested or confirmed fractures or dislocations should be splinted to avoid damage to muscles, nerves, vessels, and the skin. Splinting also may restore blood flow to ischemic tissue by removing pressure caused by a bone fragment resting against a blood vessel. Finally, splinting relieves pain; conversely, movement of fracture fragments results in severe pain.

Field Care

Splinting should begin in the field because it reduces the risk of further neurovascular compromise, prevents a closed injury from potentially being converted to an open one during transport, reduces the patient’s pain, and facilitates subsequent ED assessment and imaging. Numerous commercial devices are available, and most ambulances carry an assortment of immobilization devices (Fig. 46-12). Minimal equipment includes long and short backboards, cervical collars, sandbags, and extremity splints. A half-ring traction splint also is essential. Inflatable air splints are favored by some authors because they are convenient, easy to apply, transparent, and radiolucent and because they tamponade low-pressure bleeding. Other authors prefer to avoid these devices because theoretically they could contribute to the development of a compartment syndrome. If used, inflatable splints should be inflated only by mouth and to the point that still permits indentation by gentle finger pressure.

Field personnel should splint possible fractures before the patient is moved. Severely angulated long bone fractures should be straightened in the field before they are splinted. Splints should be applied in such a way as to immobilize the joints above and below the fracture site to avoid motion of the involved bone. The skin should be padded to avoid local necrosis, and the splint should be secured by a circumferential wrapping material. This material should allow for some expansion and should not be applied in a constricting manner.

Emergency Department Care

In the ED, the indications for splinting are the same as in the field. All splints should be checked and, if properly applied,
need not be changed. Splinting or other immobilization is also used after diagnosis and treatment of injuries. In some cases, a splint is all that is needed for definitive treatment. Injuries other than sprains and fractures (e.g., inflammatory and infectious processes, bites, burns, and repaired injuries of muscle bellies or tendons) also benefit from immobilization. Splints also can be used to improve function, such as with wrist drop that accompanies radial nerve palsy. When the injury is immobilized, it is important to stress elevation of the affected part to avoid edema formation. Many different devices and materials are available. Some devices that are commonly used are described next.

**Upper Extremity**

**Sling-and-Swathe and Velpeau Bandages.** Sling-and-swathe and Velpeau bandages are useful in immobilizing the shoulder, humerus, and elbow. They are commonly used after reduction of dislocated shoulders and to treat impacted fractures of the humeral neck. The axillae should be padded and powdered to avoid skin maceration. A commercial shoulder immobilizer also is available and is useful after reduction of a shoulder dislocation. Its advantages are ease of application and ease of removal and reaplication by the patient for bathing.

**Clavicle Splint.** Historically, middle third fractures of the clavicle routinely were initially treated with a figure-of-eight clavicle strap with or without the addition of a sling. This device is commercially available or can be fashioned from tubular stockinette. If used, a clavicle splint should be applied snugly enough to keep the shoulders back in the “at-attention” position, but not so tight as to compress the axillary artery or brachial plexus. Chafing of the skin can be avoided by padding and powdering the axillae. Superiority of the figure-of-eight clavicle strap over a simple sling has not been shown.

**Plaster and Fiberglass Splints.** Well-fitting, customized plaster splints can be fashioned easily to immobilize the elbow, forearm, wrist, and hand. The advantage of these splints is the ability to mold them to an exact size and shape (e.g., along the ulnar side of the forearm and hand to immobilize a midshaft fourth or fifth metacarpal fracture, the so-called gutter splint). Several commercially available products consist of multiple layers of plaster or fiberglass strips, inside a covering of foam and flannel, on a continuous roll that can be applied to any length. While the splint is still wet, a bandage is wrapped over it, and the splint is molded and held in the desired position as the plaster or fiberglass resin hardens.

**Forearm and Wrist Splints.** Numerous preformed splints are available for splinting fractures of the distal forearm and wrist. They are lightweight, neat, and easy to apply and are easily removed and replaced by the patient (Fig. 46-13).

**Lower Extremity**

**Femur and Hip.** Fractures of the femoral shaft can be immobilized by using a traction device, such as the Hare traction splint or a similar appliance (Fig. 46-14). These devices should be applied in the field if possible; most ambulances carry them. The principle is that a proximal ring engages the ischial tuberosity for countertraction while the longitudinal traction is applied through the ankle by means of an ankle hitch. A commercial ankle hitch is recommended, but if one is not available, an improvised hitch can be fashioned with a triangular
bandage or a wide piece of cloth tied in a Collins hitch. The patient’s ankle bones, Achilles tendon, and arch of the foot should be padded, and the circulation should be checked to ensure it is intact. A properly applied splinting device relieves pain from a fracture rather than exacerbating it.

The Sager splint might offer advantages over other appliances in that it is applied to the medial and lateral aspect of the thigh rather than having a half-ring posteriorly (Fig. 46-15). The Sager splint is more acceptable for use in the presence of pelvic fractures and avoids compression of the sciatic nerve. Because the half-ring devices may produce angulation at the fracture site, the Sager device is purported to result in better alignment, although this has never been measured. The Sager splint is shorter and more compact than the Hare traction splint, rendering it more acceptable for certain transport helicopters and body scanners. Also, the amount of traction is metered at the ankle, and overtraction can be avoided.

**Knee.** Commercially available knee immobilizers can be used after acute injuries to provide firm but not rigid stabilization of the knee. The device is essentially a foam cylinder with medial and lateral aluminum stays, attached by Velcro straps, and spanning the upper thigh to upper ankle. This device is commonly used after trauma to let the knee “cool off” until a better physical examination or diagnostic study can be performed in a few days.

Another dressing that may be applied at the knee is the Jones “compression” dressing. Some authors believe the word *compression* should not be used here to discourage application that is too tight. The Jones dressing is a bulky dressing that is used by some clinicians in situations when swelling is expected, including internal fixation procedures. The ability to flex and extend at the knee is maintained. The dressing consists of a thick layer of absorbent cotton bandage (Webril) wrapped with an elastic bandage, followed by another layer of cotton bandage, followed by an additional elastic wrap. If more stability is required, slabs of plaster can be placed on the medial and lateral side of the limb, just under the last bandage. Caution must be exercised because burns have been reported with this type of dressing when too many layers of plaster are used. A similar type of bulky dressing may be used for some injuries of the ankle and fractures of the calcaneus. In general, commercial knee immobilizers have replaced the Jones dressing in the treatment of acute knee injuries.

**Ankle.** Immobilization of the ankle can be accomplished by numerous means. Plaster splints can be used temporarily for the treatment of nondisplaced ankle fractures or for the treatment of severe sprains. These can be fashioned in the same manner as described for the upper extremity. An alternative method is to apply a full circular cast, bivalve it on either side, discard the anterior piece, and affix the posterior mold with an elastic bandage or bias-cut stockinette. Most ankle injuries should be splinted with the patient’s ankle in neutral position.
Injuries to the Achilles tendon, plantaris muscle, or gastrocnemius muscle initially should be treated with the foot held in slight equinus (plantar flexion) for comfort. The toes should be free to move distal to the metatarsophalangeal joints, and the proximal border should end below the tibial tubercle to avoid pressure on the peroneal nerve.

Adhesive strapping is an alternative method of ankle immobilization that provides good support and limitation of motion. Taping reportedly loses its “protective properties” with cyclic loading and sweating; although this is cited as a disadvantage, it may actually be helpful in encouraging and allowing early mobilization. This method is lightweight and not bulky, and a shoe can be worn over it. Tape is applied in a noncontinuous manner, which allows for swelling and avoids constriction. First, the hair is shaved. Next, strips of tape are measured and torn off; 1½-inch or 2-inch cloth-backed adhesive tape or Elastoplast is used. Elastoplast is an elastic-backed tape, constructed to stretch only in the longitudinal direction; this serves to spring the foot back automatically to a neutral position if the foot is plantar-flexed for any reason. The tape should be applied directly to the skin after a skin adherent, such as tincture of benzoin, is applied. The tape should lie flat because wrinkles may damage the skin (Fig. 46-16).

A dome-paste bandage, or Unna’s boot, is a bandage impregnated with zinc oxide, calamine lotion, glycerin, and gelatin that also is well suited to immobilizing an ankle sprain. This combination is gentle to the skin, which is especially important if atrophy or venous incompetence is present. In addition, hair need not be shaved, the bandage is easy to apply, and a shoe can be worn over it. Some patients complain about the sticky sensation against the skin, especially in warm weather. Another disadvantage is that it is applied concentrically, and problems can arise if the bandage is wrapped too tightly. The bandage should be applied directly to the skin, starting at the foot and working upward; it should overlap at each turn approximately half the width of the previous turn and continue up to just below the tibial tubercle. Then the bandage should be covered with either bias-cut stockinette or an elastic bandage. The dome-paste bandage hardens to about the consistency of sturdy cardboard and provides firm support. Removal is best accomplished with bandage scissors.

An increasingly preferred device for moderate to severe lateral ankle sprains is a commercial support composed of molded plastic with Velcro straps (e.g., Air Cast, AirStirrup) (Fig. 46-17). This product may be worn in the patient’s shoe and permits early weightbearing and return to activity. It is designed to permit dorsiflexion and plantar flexion but to limit inversion and eversion, a concept referred to as functional bracing. Some authors also find this device useful during athletic activities instead of adhesive taping to prevent recurrences. Although these orthoses are relatively expensive, the cost might be more than offset by their ease of application, their reusability, and the benefit derived from earlier return to work.

Severe ankle sprains also may benefit from immobilization in a CAM Walker, which is a commercial appliance consisting of a layer of padding extending from the tibial tubercle to the metatarsal heads, supported by metal plates along the length of the lower leg. These plates articulate with a molded hard plastic boot at the ankle. The position of the foot can be adjusted as desired, and when set, the ankle is kept firmly immobile. The rounded undersurface of the boot allows for ambulation without movement of the ankle joint.

Casts

Plaster casts perform a function similar to splints in that they provide stability and pain relief. Casts sometimes are used in
that can be molded into a cast. An exothermic reaction takes place that causes the plaster to harden and can burn the skin.85 Factors that have been shown experimentally to increase skin temperatures during plaster application are dip-water temperatures greater than 24°C, cast thickness greater than eight plies, and inadequate ventilation of the newly applied cast.

Immersion of the plaster in water for too short a time or squeezing too much water out also may lead to generation of excess heat. To avoid pressure on the skin and over bony prominences, stockinette and layers of cotton sheet wadding (Webril) are snugly applied first. Padding that migrates under a formed cast can be uncomfortable and result in pressure sores. Padding alone does not prevent burns.86

Variations of the basic cast exist. A window may be placed in the cast, and the cutout area may be used as access to skin wounds that require care during immobilization. Walking heels may be worked onto a lower extremity cast and should be placed in the center of the foot. Synthetic casts (fiberglass and other materials) are lightweight, durable, and water-resistant. In addition, their setting temperatures are significantly lower, and they are less likely to produce burns.87 However, they are more expensive and more difficult to apply.

Patients with casts may present to the ED for complaints related to their casts; these usually are pain, local irritation, swelling, or numbness of the distal part. A cast that is too tight results in swelling, pain, coolness, and change in skin color of the distal parts. Pain also may be caused by the initial injury or by local pressure, or it may be a result of a developing compartment syndrome or wound infection. The safest thing to do if a patient complains of pain is to bivalve the cast and inspect the extremity. This is done by cutting the plaster and the padding on each side and removing half the cast at a time, using the other half as a mold to keep the extremity immobile. Afterward, the bivalved cast can be held together with bias-cut stockinette or elastic wrap until a new cast is applied. If relieving external pressure does not alleviate symptoms, the diagnosis of compartment syndrome should be seriously considered.

Casts may obscure wound infections, sources of sepsis, and even the source of tetanus. The clinician should not hesitate to bivalve the cast and inspect the extremity.

The need for mandatory routine cast checks 1 day after initial application has been questioned.88 In a retrospective study of 250 patients, none experienced problems from neurovascular compression, although 24% required some alteration of the cast. In the study, it may be simply that the casts were applied incorrectly in the first place. It is probably advisable to continue routine cast checks if casts are applied in the ED.

**Thermal Therapy**

Some confusion exists as to the role of cryotherapy versus heat therapy in the treatment of acute orthopedic injuries. Part of this confusion arises because heat may be more soothing to the patient. Cold causes vasoconstriction, limiting blood flow and hemorrhage into the traumatized area. Metabolic requirements are reduced in cooled tissues, as is histamine, and less capillary breakdown occurs as a result. Reduced blood flow also limits edema formation. Lower extravascular fluid pressure allows for better lymphatic drainage of injured areas. Cryotherapy produces three, and perhaps four, stages of sensation of which the physician and the patient should be aware. In the first stage, a cold sensation is noted for 1 to 3 minutes. The second stage consists of a burning or aching sensation for 2 to 7 minutes after the application of cold. This stage is uncomfortable, but must be endured to receive the benefits of the next two stages. Heat therapy, by contrast, is soothing,
and patients are likely to prefer this to the second stage of cryotherapy. The third stage begins 5 to 12 minutes after the application of ice and produces local numbness or anesthesia. The pain-spasm cycle is interrupted. While under this anesthetic effect, passive exercise may be desirable. This exercise helps to prevent atrophy, mobilize edema, clear injury debris, and reduce adhesions. However, several reviews of cryotherapy for soft tissue injury all reflect the lack of adequate science in establishing recommendations for cryotherapy. Application of ice appears to be effective in reducing pain, but there is no credible evidence that it accelerates healing. A fourth stage sometimes occurs 12 to 15 minutes after intense cryotherapy is begun, consisting of reflex deep tissue vasodilation without a corresponding increase in metabolism (reminiscent of the situation in rewarming shock). Because of this, a maximum of 15 minutes of cold application per treatment usually is advised. An experimental study using triple-contrast bone scans compared the effect of icing times from 5 to 25 minutes on blood flow to the knee. Five minutes produced a measurable decrease in all tissues of the knee, whereas 25 minutes increased this effect fourfold and produced the overall maximal effects. A paradoxical increase in blood flow, perhaps reflecting reflex vasodilation, occurred at 10 minutes but then reversed. These results suggest that longer icing times than previously recommended may be beneficial. Absolute contraindications to cryotherapy include severe cold allergy (with hives and joint pain) and Raynaud’s phenomenon and disease. Relative contraindications include some rheumatoid conditions and paroxysmal cold hemoglobinuria with renal dysfunction and secondary hypertension. Anesthetic skin in a paralyzed or comatose patient is at risk with ice therapy. One case of gangrene has been reported, but in this instance cold was applied for 16 hours a day for 2 months. These contraindications to cryotherapy are rare, especially in the athletic population most at risk for serious injuries. Heat increases blood flow and the inflammatory response and edema. Warm tissues and cells have a higher metabolic rate and increased requirements of nutrients and oxygen. Ice, rather than heat, is the method of choice of most authorities in the acute treatment and rehabilitation of acute orthopedic injuries and should be initiated as soon as possible for maximum benefit.

### KEY CONCEPTS

- Compartment syndrome is associated most commonly with a closed long bone fracture of the tibia but also is well described in the thigh, forearm, arm, hand, and foot and can occur with soft tissue trauma alone. Elevation of a limb with resultant reduction in the local arteriovenous gradient may be counterproductive and may exacerbate compartment syndrome.
- Because of their blood supply, certain bones may undergo avascular necrosis after fracture, especially if fractures are comminuted and go untreated for any length of time. The femoral head, talus, scaphoid, and capitate are particularly prone to this complication.
- Fat embolism syndrome is a serious manifestation of fat embolism, occurring most commonly after long bone fractures in young adults (usually tibia and fibula) and after hip fractures in elderly patients. Respiratory distress syndrome is the earliest, most common, and serious manifestation. Neurologic involvement, manifesting as restlessness, confusion, or deteriorating mental status, is also an early sign, as are thrombocytopenia and a petechial rash.
- In children, epiphyseal fractures occur more commonly than ligamentous disruption because of the relative ligamentous strength compared with the ease of disrupting the epiphyses.

CHAPTER 47 Hand

Everett T. Lyn and Thomas Mailhot

PERSPECTIVE

The hand is intricate, dynamic, and unique in function. It combines extreme mobility, precision, power, and sensation and is used to express and execute. Because the hands are used more to manipulate the environment than the rest of the body, they are commonly injured. Function depends on intact relationships among intrinsic structural components, musculoskeletal tendinous units originating from more proximal areas, and motor and sensory connections with the central nervous system. Restoration of function rather than appearance is the primary goal in management of hand injuries and infections. Early recognition and timely initiation of therapy for limb-threatening conditions are essential to an optimal outcome. The fate of the injured hand depends largely on the physician who provides initial care. Mismanagement may result in unnecessary functional loss that may not be recoverable, even with the best convalescent care. An understanding of the functional anatomy of the hand is necessary for the appropriate evaluation and management of these disorders.

Epidemiology

Overall, hand injuries are reported to represent 5 to 10% of visits to an emergency department (ED), and approximately 6% of the patients have deep, significant injuries. Injuries have environmental, occupational, and recreational causes and are seen in all age groups. The spectrum of injury includes infections, lacerations, fractures, crush wounds, amputations, and burns. It is estimated that 10% of all patients with hand injuries require referral to a hand specialist, and most patients referred from EDs have fractures. The disability potential of hand injuries generally is high; such disability may involve the surface anatomy of the hand be used (Fig. 47-1). The back of the hand and fingers is called the dorsal surface, and the palm side is called either the palmar or the volar surface. The borders of the hand are radial and ulnar. The five digits often are designated by numerals, but common names are preferable: I (thumb), II (index finger), III (long or middle finger), IV (ring finger), and V (little finger). Each finger has three joints: the metacarpophalangeal (MCP), the proximal interphalangeal (PIP), and the distal interphalangeal (DIP) joints. The thumb has an MCP joint and only one interphalangeal (IP) joint. There are proximal, middle, and distal phalanges in the fingers and only a proximal and a distal phalanx in the thumb. The thenar mass or eminence refers to the muscular area on the palmar surface overlying the thumb metacarpal. The hypothenar eminence is the muscle mass on the palmar surface overlying the little finger metacarpal.

Hand and digit motion has been standardized and is illustrated in Figures 47-2 through 47-6. The carpometacarpal (CMC) joint is more mobile in the thumb than in the other fingers and is the key to the grasp and dexterity that characterize the human hand. Motions of this joint include palmar abduction (also called flexion), radial abduction, retroposition (extension), adduction, and opposition (see Fig. 47-6). The IP joints are essentially hinge joints and are capable of only two motions: flexion and extension.

Structural Framework

Skin Cover

The hand has two skin surfaces, each with different functions. The skin of the palm is thick compared with the dorsal skin and is stabilized by fibrous connections on its deep surface. The skin creases in the palmar aspect of the hand are largely transverse and represent adherence between skin and underlying fascia, without intervening adipose tissue. These features facilitate flexion and limit the development of inflammatory edema in the palm. The other noteworthy characteristic of the palmar skin is the unique arrangement of epithelial ridges of the dermis that form cutaneous striations. These ridges have forensic importance in the pulp as “fingerprints” and play an important role in increasing friction for grasping objects. The dorsal skin is relatively thin and mobile, permitting motion of the various joints. As a path of least resistance, the dorsum of the hand also swells easily after inflammation or trauma, which may limit flexion of the MCP joints. In addition, infection in the palmar aspect of the hand may cause
Skeleton

The hand and wrist contain 27 bones: 14 phalangeal bones, 5 metacarpal bones, and 8 carpal bones (Fig. 47-7). The eight small carpal bones in the region of the wrist are strongly united to one another by ligaments. These bones form synovial joints and are arranged in two rows, proximal and distal, with four bones in each row. Together the bones of the carpus present a concavity on their volar surface, which is bridged by a strong dorsal swelling; this finding can be misleading without a careful physical examination.
membranous band, the flexor retinaculum. In this way, the bridge and the bones form a tunnel, known as the carpal tunnel, through which pass the median nerve and the long flexor tendons of the fingers. The IP joints are inherently more stable than the MCP joint, by virtue of their bicondylar configuration, which gives a modified tongue-in-groove appearance (Fig. 47-8).

The soft tissue supporting these joints includes the capsular ligamentous structures, which afford stability, and the tendinous structures, which generate mobility. The metacarpal and IP joints are stabilized on both sides by collateral ligaments and anteriorly by a palmar fibrocartilaginous “volar plate.” Because of anatomic differences between the metacarpals and phalanges, the IP collaterals are tight throughout the entire range of motion, whereas the collaterals of the MCP joint are tightest in flexion (Fig. 47-9). The IP joints are hinges, but the MCP joint has additional side-to-side mobility and rotational movement to facilitate efficient grasp. The clinical importance of these differences is that to minimize the development of contractures after joint injuries, the preferred position of immobilization of the PIP joints is extension, whereas the MCP joints are more properly placed in flexion.

The structure and arrangement of the metacarpals are noteworthy. The metacarpals participate in three arches: the proximal (carpal) and distal (metacarpal) transverse arches and the longitudinal arch (Fig. 47-10). The index and long finger metacarpals form a fairly immobile segment because of their ridged articulation with the carpals. The adjacent metacarpals are more mobile. This unique anatomy gives the human palm a longitudinal and transverse concavity when the thumb is...
alongside the index finger; however, this changes to an oblique gutter when the thumb is extended.

The small bones of the child’s hand differ significantly from the bones of the adult and from other long bones because of the presence of an epiphysis or growth plate at one end of the bone. The phalangeal epiphyses and the thumb metacarpal epiphysis are located at the proximal end, and the finger metacarpal epiphyses are located at the distal end of the bone (Fig. 47-11). In boys, the proximal phalangeal epiphysis appears at 15 to 24 months and fuses at 16 years. In girls, it appears at 10 to 15 months and fuses at 14 years. The time of appearance and fusion is related to skeletal maturity and can be judged accurately until puberty from hand and wrist radiographs, because the sequence of development is age-specific.

Muscle and Tendon Function

The muscles that power the hand may be divided into extrinsic and intrinsic muscles. The intrinsic muscles have their origins and insertions within the hand. The extrinsic muscles have origins in muscle bellies in the forearm and tendinous insertions on bones in the hand. They are divided further into extrinsic flexor and extensor muscles. The flexors of the digits in the hand lie on the volar surface of the forearm; the extensors are on the dorsal surface.

Intrinsic Musculature

The intrinsic muscles of the hand include the muscles of the thenar and hypothenar eminences, the adductor pollicis, the interossei, and the lumbricals (Fig. 47-12). The thenar muscles cover the thumb metacarpal. This group includes the abductor pollicis brevis, opponens pollicis, and flexor pollicis brevis. These muscles originate in the flexor retinaculum and on the carpal bones and insert at the base of the first metacarpal and first proximal phalanx. They act in concert with the long flexors and extensors to carry the thumb through its intricate range of motion. The muscles are evaluated by palpating the thenar eminence for contraction as the patient brings together the tips of the thumb and little finger. They also can be tested by asking the patient to place the dorsum of the hand on a flat surface and to raise the thumb up straight to form a 90-degree angle with the palm. The thenar muscles usually are innervated by the motor branch of the median nerve. In some cases, they may be partially innervated by the ulnar nerve.

The adductor pollicis arises from the second and third metacarpals and inserts on the first proximal phalanx. This muscle is innervated by the ulnar nerve. Thumb adduction is tested separately by having the patient forcibly hold a piece of paper between the thumb and radial side of the index proximal phalanx. If the adductor pollicis is weak or nonfunctioning, the thumb IP joint flexes with this maneuver (Froment’s paper sign). In this evaluation, the two hands should be compared.

The lumbrical muscles arise from the sides of the flexor digitorum profundus (FDP) tendons; the interossei muscles lie between the metacarpal bones and originate from them. Both of these muscle groups insert in the extensor expansions of digits II to V and act on the fingers to flex the MCP joints and extend the IP joints. The radial two lumbricals are innervated by the median nerve, and the ulnar two are innervated by the ulnar nerve. The seven interossei (three palmar and four dorsal) can be considered together. They lie on either side of the finger metacarpals and are innervated by the ulnar
The patient abduct and extend the thumb with resistance applied to the thumb; they can be palpated on the radial side of the wrist during this maneuver.

Two tendons lie in the second compartment: the extensor carpi radialis longus and brevis. These tendons insert at the dorsal base of the index and middle metacarpals. They act primarily to extend and deviate the wrist radially. These tendons can be palpated by having the patient extend the wrist against resistance while making a fist.

In the third compartment, a single tendon, the extensor pollicis longus, arises from the deep muscles of the midforearm, passes around a bony prominence on the dorsum of the wrist termed *Lister’s tubercle*, and inserts on the base of the distal phalanx of the thumb. This tubercle can be palpated just proximal to the wrist joint. The extensor pollicis longus forms the dorsal border of the anatomic snuffbox, and the abductor pollicis longus forms the volar border (Fig. 47-14). The floor of this area contains the radial artery and two carpal bones, the scaphoid and trapezium. The extensor pollicis longus functions to extend and adduct the entire first ray and extend and hyperextend the IP joint of the thumb. This muscle is evaluated by placing the hand flat on a table and having the patient lift only the thumb off the surface. Because the abductor pollicis brevis and the adductor pollicis add terminal extension, complete laceration of the extensor pollicis longus tendon may not eliminate the patient’s ability to extend the thumb.12

The tendons that extend the fingers—the extensor indicis proprius and the extensor digitorum communis—are in the fourth compartment. The extensor digitorum muscle divides into four tendons proximal to the wrist. In the dorsum of the hand, these tendons are connected by juncturae, which help stabilize them to their insertions in the extensor expansions of digits II to V. The tendon to the index finger is joined on its radial side by the tendon of the extensor indicis proprius. The tendon to the little finger is joined on its ulnar side by two slips from the extensor digiti minimi. The extensor digiti minimi is contained in the fifth dorsal compartment and lies...
The extensor mechanism of each digit is a complex interrelationship of muscle tendon units of the long extrinsic extensor tendons and the intrinsic system (Fig. 47-15). The extensor expansion divides into a central slip that attaches to the middle phalanx and two lateral bands that join with the tendons of the lumbrical and interosseous muscles and attach to the base of each distal phalanx. The interossei and lumbrical muscles insert in the lateral aspects of the dorsal hood. Most of the power of the common extensors serves to extend the MCP joint. Distal digit extension is provided by continuation of the lateral band mechanism and the oblique retinacular ligament. Because of this complex anatomy, injuries involving the extensor mechanism require meticulous repair.

The sixth compartment contains the extensor carpi ulnaris. This tendon passes distal to the head of the ulna on the ulnar aspect of the wrist and inserts on the base of the little finger metacarpal. The extensor carpi ulnaris functions to extend and deviate the wrist ulnarly. This tendon is evaluated by having the patient extend and push the hand to the ulnar side against resistance; the tendon can be palpated distal to the ulnar styloid process.

**Flexor Tendons**

The flexor tendons reside on the volar side of the forearm and cross the wrist joint volar to its axis. Generally, 12 tendons function to flex the wrist and digits; 3 of them—the flexor carpi radialis, flexor carpi ulnaris, and palmaris longus—primarily flex the wrist and deviate the wrist radially or ulnarly (Fig. 47-16). The remaining tendons pass into the digits through the carpal tunnel. A single tendon, the flexor pollicis longus, inserts on the distal phalanx of the thumb, and two flexor tendons go to each remaining finger. The flexor digitorum superficialis (FDS) tendons bifurcate near the base of the proximal phalanges and surround the tendons of the FDP before inserting on the middle phalanges of digits II to V (Fig. 47-17). The FDS flexes all of the joints it crosses, including the wrist, PIP joints, and MCP joints. The profundus tendons lie deep to the superficialis tendons over most of their course in the forearm. At the level of the MCP joint, they perforate the superficialis tendon to emerge to a superficial position. They insert at the base of the distal phalanx and act primarily to flex the DIP joint and all joints flexed by the FDS. From the level of the MCP joint

---

**Figure 47-13.** A, The extensor tendons gain entrance to the hand from the forearm through a series of six canals, five fibro-osseous and one fibrous (the sixth dorsal compartment, which contains the extensor digiti quinti proprius [EDQP]). The first compartment contains the abductor pollicis longus (APL) and extensor pollicis brevis (EPB); the second, the radial wrist extensors; the third, the extensor pollicis longus (EPL), which angles around Lister’s tubercle; the fourth, the extensor digitorum communis (EDC) to the fingers and the extensor indicis proprius (EIP); the fifth, the EDQP; and the sixth, the extensor carpi ulnaris (ECU). The communis tendons are joined distally near the metacarpophalangeal joints by fibrous connections called juncturae tendinum. Beneath the retinaculum, the extensor tendons are covered with a synovial sheath. B, The proprius tendons to the index and little fingers are capable of independent extension, and their function may be evaluated as depicted. With the middle and ring fingers flexed into the palm, the proprius tendons can extend the ring and little fingers. ECRB, extensor carpi radialis brevis; ECRL, extensor carpi radialis longus. (From Doyle JR: Extensor tendons—acute injuries. In Green DP [ed]: Operative Hand Surgery. New York, Churchill Livingstone, 1993, p 1927.)

ulnar to the small finger extensor. The extensor indicis lies ulnar and deep to the index extensor. The dual extensor system for the index and small fingers gives these two digits extension independent of the other digits. The middle finger and especially the ring finger have considerably limited independent extension. The restrictive motion is due to the junctura, which also prevents retraction of the proximal tendon end after distal division of an extensor. Complete division of an extensor proximal to the junctura can be associated with normal MCP joint extension. This extension occurs through the junctura connection. The extensor digitorum communis tendons can be evaluated by asking the patient to straighten out all of the fingers. The function of the extensor indicis proprius can be isolated from the common extensors by asking the patient to make a fist and then to point the second digit. The extensor digiti minimi is examined by having the patient straighten the little finger while the hand is closed into a fist.
Figure 47-15. The extensor tendon at the metacarpophalangeal (MP) joint level is held in place by the transverse lamina or sagittal band, which tethers and centers the extensor tendons over the joint. This sagittal band arises from the volar plate and the intermetacarpal ligaments at the neck of the metacarpals. Any injury to the extensor hood or expansion may result in subluxation or dislocation of the extensor tendon. The intrinsic tendons from the lumbrical and interosseous muscles join the extensor mechanism at approximately the level of the proximal and midportion of the proximal phalanx and continue distally to the distal interphalangeal (DIP) joint of the finger. The extensor mechanism at the proximal interphalangeal (PIP) joint is best described as a trifurcation of the extensor tendon into the central slip, which attaches to the dorsal base of the middle phalanx and the two lateral bands. These lateral bands continue distally to insert at the dorsal base of the distal phalanx. The extensor mechanism is maintained in place over the PIP joint by the transverse retinacular ligaments. (From Doyle JR: Extensor tendons—acute injuries. In Green DP [ed]: Operative Hand Surgery. New York, Churchill Livingstone, 1993, p 1928.)

Figure 47-16. Palmaris longus accentuation.

Figure 47-17. Anatomy of flexor digitorum superficialis (FDS) and profundus (FDP) in the finger. (From Schneider LH: Flexor Tendon Injuries. Boston, Little, Brown, 1985.)

Figure 47-18. The flexor pulley system. The pulleys are thickenings in the fibrous flexor sheath. There are five annular pulleys (transversely oriented fibers) (A1 to A5). There are four cruciate pulleys (oblique with some crisscrossing fibers) (C1 to C4). (Courtesy of Kleinert, Kutz and Associates Hand Care Center.)
against resistance. FDP function can be tested by having the patient flex the distal phalanx of each finger while the PIP is stabilized in extension by the examiner (Fig. 47-19). The FDS is tested individually by asking the patient to flex the PIP joint while the other fingers are held in extension to block the flexion produced by the profundus tendons (Fig. 47-20). This is a subtle but important distinction, because lacerations of the digital creases can easily damage one or more of the tendons or adjacent neurovascular bundles. The FDP is more commonly lacerated in the finger because of its paradoxically superficial position.

If movement against resistance is intact but accompanied by pain or diminished strength, the involved tendon may be partially disrupted. Pathologic nodular swelling of one of the long flexor tendons may result in intermittent catching, or “triggering,” on a thickened flexor sheath anterior to the MCP joint. In this condition, known as trigger finger, a palpable and sometimes audible snapping can be appreciated when the patient is asked to flex and extend the fingers. Steroid injections have been suggested as first-line treatment for trigger finger in nondiabetic patients.13

**Synovial Spaces**

Bursae are synovial sheaths that cover tendons as they pass through osseofibrous tunnels. They contain synovial fluid and serve two essential functions: They decrease friction during tendon movement, and they help supply nutrients to the relatively avascular tendons (Fig. 47-21). These sheaths also can provide pathways for spread of infection. Extensor tendons do not lie within definite sheaths and are afforded a greater resistance to infections. The synovial sheaths of the flexors in the index, middle, and ring fingers are enclosed from their insertion to approximately the level of the distal palmar crease. The sheath of the flexor pollicis longus extends from the tip of the thumb to the proximal volar wrist crease, where it communicates with the radial bursa in the palm and carpal tunnel. Similarly, the synovial sheath of the little finger communicates with the ulnar bursa. Clinical features of flexor tenosynovitis are caused by inflammation and distention of these synovial sheaths. Kanavel14 described the classic signs: a flexed posture of the digits, pain on passive extension of the digits, incomplete flexion, and tenderness of the synovial sheath.

**Blood Supply**

**Arterial System**

The hands and the digits have a dual blood supply (Fig. 47-22). The major blood supply to the hand is from the radial and ulnar arteries. The radial artery lies on the anterior aspect of the radius in the distal part of the forearm. It continues around the lateral side of the wrist onto the dorsum of the hand by passing deep to the tendons of the abductor pollicis longus and the extensor pollicis brevis. On entering the palm, the radial artery terminates as the deep palmar arch. The ulnar artery enters the hand anterior to the flexor retinaculum on the radial side of the ulnar nerve and pisiform bone. The artery gives off a deep branch and then continues into the palm as the superficial palmar arch. This complex arterial arch system anastomoses and sends branches to the individual digits and the deep palmar spaces. Because of extensive collateralization, the hand usually survives even if both vessels are transected at the wrist.15 The circulation of the hand is evaluated by palpating the radial and ulnar arteries on the volar aspect of the wrist, by passing deep to the tendons of the abductor pollicis longus and the extensor pollicis brevis. On entering the palm, the radial artery terminates as the deep palmar arch. The ulnar artery enters the hand anterior to the flexor retinaculum on the radial side of the ulnar nerve and pisiform bone. The artery gives off a deep branch and then continues into the palm as the superficial palmar arch. This complex arterial arch system anastomoses and sends branches to the individual digits and the deep palmar spaces. Because of extensive collateralization, the hand usually survives even if both vessels are transected at the wrist.15 The circulation of the hand is evaluated by palpating the radial and ulnar arteries on the volar aspect of the wrist, by assessing the color and warmth of the skin, and by testing capillary refill. Because “normal” findings vary among patients, the injured hand should be compared with the unaffected side.
Although *Allen’s test* is an imperfect predictor of vascular compromise, it is commonly used to determine the patency of the arteries supplying the hand and the contributions to the circulation of the hand derived from each of the major vessels. The radial and ulnar arteries are compressed by the examiner at the wrist (Fig. 47-23). The patient opens and closes the hand repeatedly to exsanguinate it and then maintains a relaxed position. The radial artery is released. If the palm and fingers fill immediately with blood, the radial artery is patent, with good collateral flow into the ulnar artery system. To evaluate the ulnar artery, the same steps are repeated, but the ulnar artery is released. This method also can be used on a single digit to help evaluate the patency of each digital vessel to that finger. Similar to the hand, the digit usually survives even if both digital vessels are transected at the base of the finger; however, healing of associated injuries may be delayed or may be compromised by excessive scar formation because of associated, although relative, ischemia.¹⁵

### Venous and Lymphatic Systems

The veins generally follow the arterial pattern in the deep system. The abundant dorsal, superficial veins are more extensive than the deep system and drain most of the blood from this region. The lymphatic vessels essentially follow the veins, with most lymph flowing into channels in the dorsal subcutaneous space. This vascular anatomy and the laxity of the dorsal skin account for palmar infections causing swelling on the dorsum rather than on the palmar surface of the hand.

### Nerve Supply

The nerve supply to the hand comes from the radial, ulnar, and median nerves. All three nerves control movement of the wrist, fingers, and thumb. In the hand, the ulnar and median nerves are mixed motor and sensory nerves, whereas the radial nerve is purely sensory. Each of the three major nerves passes
through a muscle in the forearm, and each passes points of potential entrapment en route to the hand.

**Motor Innervation**

The radial nerve (formed from nerve roots C6 through C8) passes through the supinator muscle and enters the dorsal aspect of the wrist between the radial styloid and Lister's tubercle. At this level, the nerve has a purely sensory function. Its important motor function is to innervate the dorsal extrinsic muscles in the forearm, which extend the wrist and MCP joints and abduct and extend the thumb. No intrinsic muscles in the hand are innervated by the radial nerve. Motor function in this nerve is tested by having the patient extend the wrist against resistance. Proximal injury to the radial nerve causes a condition known as **wristdrop**: The fingers are held in flexion at the MCP joints, and the thumb is adducted (Fig. 47-24A).

The ulnar nerve (C7, C8, and T1) passes through the flexor carpi ulnaris muscle in the forearm and lies ulnar to the artery and superficial to the flexor retinaculum. It enters the hand at the wrist through the **ulnar tunnel**, or **Guyon's canal**. The ulnar nerve innervates the hypothenar muscles, the seven interosseous muscles, the lumbricals to the ring and little fingers, and the adductor pollicis. Innervation of the flexor pollicis brevis is variable. In the forearm, the flexor carpi ulnaris and the ulnar half of the FDP also are innervated by the ulnar nerve. Loss of motor function of the ulnar nerve results in inability to pinch a piece of paper tightly between the thumb and the index finger. A late characteristic of distal ulnar damage is Duchenne’s sign, manifested by clawing of the ring and little fingers (see Fig. 47-24B). The ring and little fingers are hyperextended at the MCP joints by the extensor digitorum communis (radial nerve) and flexed at the IP joints by the FDP (intact proximal ulnar nerve). In addition, the interosseous and hypothenar muscles are atrophied.

The median nerve enters the forearm through the pronator teres muscle. At that level, it innervates that muscle, the flexor carpi radialis, the FDS, the radial part of the FDP, the flexor pollicis longus, and the pronator quadratus. The branch of the median nerve that innervates the last three muscles is called the **anterior interosseous nerve**. The median nerve enters the hand through the carpal tunnel accompanied by the nine extrinsic flexor tendons of the digits. The thenar motor branch (recurrent median nerve) innervates the adductor pollicis brevis, the opponens pollicis variably, and the flexor pollicis brevis. Common digital branches innervate the lumbricals muscles to the index and long fingers. Injury to this nerve occurs most commonly at the level of the wrist, by laceration or by compression in the carpal tunnel. Motor function is tested by having the patient oppose the thumb to the index digit. Injury to the median nerve in the upper forearm or at the elbow usually results in weakness or absence of flexion of the index finger distal phalanx, the middle phalanx, and the thumb and weakness of thumb abduction and opposition. With passage of time, the muscles of the thenar eminence atrophy, leaving the hand with a flattened and “apelike” appearance (see Fig. 47-24C).

**Sensory Innervation**

The typical distribution of the sensory nerves to the hand is shown in Figure 47-25. Because some overlap occurs between various sensory nerves, it is preferable to test sensation in the areas least likely to have dual innervation. The anatomic area of least ulnar variation and overlap is the volar tip of the little finger. The median nerve exclusively innervates the volar tip of the index finger. The dorsal first web space is entirely represented by the median nerve that innervates the last three muscles is called the “anterior interosseous nerve.” The median nerve enters the hand through the carpal tunnel accompanied by the nine extrinsic flexor tendons of the digits. The thenar motor branch (recurrent median nerve) innervates the adductor pollicis brevis, the opponens pollicis variably, and the flexor pollicis brevis. Common digital branches innervate the lumbricals to the index and long fingers. Injury to this nerve occurs most commonly at the level of the wrist, by laceration or by compression in the carpal tunnel. Motor function is tested by having the patient oppose the thumb to the index digit. Injury to the median nerve in the upper forearm or at the elbow usually results in weakness or absence of flexion of the index finger distal phalanx, the middle phalanx, and the thumb and weakness of thumb abduction and opposition. With passage of time, the muscles of the thenar eminence atrophy, leaving the hand with a flattened and “apelike” appearance (see Fig. 47-24C).

Several methods exist to assess sensation. The preferred method, which is most accurate and objective, is comparative two-point discrimination. An uninjured hand is able to distinguish two points that are 2 to 5 mm apart at the fingertips and 7 to 10 mm apart at the base of the palm. The dorson of the hand is the least sensitive region, with a normal threshold at 7 to 12 mm. Two-point threshold distances wider than these ranges indicate impaired sensory function. The threshold and two-point discrimination tests may be of limited value in...
children, patients with heavily calloused fingertips, uncooperative patients, comatose patients, patients in severe pain, or suspected malingers.

**Fingertip**

The fingertip generally is defined as the area distal to the insertion of the flexor profundus and extensor tendons (Fig. 47-26). The pulp is the tissue of the fingertip between the volar skin and the distal phalangeal bone. The fingertip is well padded by adipose tissue and is covered by highly innervated skin that is tethered to the distal phalanx by a series of fibrous septa. The dorsal skin is thinner and less vascularized than the volar skin. Sensation is supplied by nerves that travel with arteries bilaterally along the radial and ulnar aspects of the fingers. The arteries branch to form volar anastomoses or arches similar to those in the palm. Dorsal branches supply the nail bed and matrix.

**Nail**

The nail (or nail plate) consists of compacted scales that originate from cornified epithelial cells. The proximal part of the nail is called the root; it emerges from a groove in the skin to form the body of the nail, which is exposed. The root of the nail is covered by a fold in the skin called the proximal nail fold. A small portion of the epidermis of the nail fold extends out over the proximal body of the nail to form the cuticle, or eponychium. The floor of the nail plate or nail bed is composed of tissue known as the nail matrix. The distal skin of the nail bed complex is called the hyponychium. The skin overlying the nail laterally is called the perionychium. The semicircular white crescent region near the nail fold is called the lunula.

The nail bed complex on the dorsum of the fingertips is important in providing additional stabilization of the palmar soft tissues against compression and shear forces. The nail grows from the nail matrix along the nail bed and is firmly adherent to the bed. It is now believed that the entire nail bed is active in the generation and migration of the nail. As new nail forms, it glides forward over the nail bed at a rate of approximately 0.5 to 1.2 mm per week (toenails grow much more slowly). The nail itself is a hard, firm, and relatively translucent structure; the underlying vascular tissue showing through gives the nail its pink appearance. A smooth nail bed is essential to normal function. If the nail bed sustains injury that is not repaired accurately, granulation tissue forms scar that impedes normal nail production and growth. The result may be a split or absent nail that is cosmetically unappealing and sometimes functionally debilitating.

---

**CLINICAL FEATURES: SIGNS AND SYMPTOMS**

The initial evaluation of an acutely injured hand is crucial because it affords the best opportunity for accurate assessment of the extent of damage and for restoration of altered anatomy. Evaluation of any hand injury should begin by obtaining the historical facts of the patient's age, occupation, hand dominance, and previous hand impairment or injury. In traumatic injuries, elapsed time since the injury, mechanism of injury, posture of the hand at the time of injury, and treatment before arrival in the ED are all useful data. In nontraumatic problems, pain, swelling, sensory change or contracture, timing of symptoms, presence of similar symptoms in other extremities, aggravating or alleviating factors, and functional impairment are useful historical points. A review of the medical history and a review of systems complete the evaluation.

After a detailed history is taken, the entire extremity should be exposed and evaluated when the hand is examined. A system of priorities, based primarily on threat to ultimate function, should direct the sequence of the examination. In order of priority, the examination includes evaluation of vascular and neurologic integrity, skin cover, skeletal stability, and joint and tendon function (Box 47-1). The general appearance of the

hand should be noted, with focus on its color, presence of swelling or edema, and any abnormal posture or position. In traumatic injuries, the precise area of maximal tenderness should be localized. Rotational, angular, and shortening deformities should be noted with regard to direction and extent. Angular deformity may be seen best with the fingers in full extension. Rotational deformity is best observed during digital flexion. Digital or wrist block anesthesia may be helpful in some cases to accurately assess fracture deformity and stability during digital motion and, if necessary, stress testing. Open wounds should be assessed with regard to location, relationship to skin creases, direction and viability of skin flaps, extent of skin loss, degree of contamination of the wound, and extent of soft tissue injury. The examiner must have a sterile field, good light, adequate exposure, and a nearly bloodless field for a thorough evaluation. The complete examination also may require an evaluation of active shoulder motion, elbow motion, and pronation and supination of the forearm and assessment of the contralateral hand.

**DIAGNOSTIC STRATEGIES: RADIOLOGY**

Despite the development of numerous new and sophisticated imaging techniques, plain radiography remains the most important imaging modality for the hand and wrist. The standard radiographic series of the hand should include a postero-anterior, a true lateral, and an oblique projection (Fig. 47-27). With correct positioning, the bones do not overlap on the film, allowing complete evaluation of each area for visualization of fractures, subluxation, dislocation, deformities, and retained radiopaque foreign bodies. Open wounds should be assessed with regard to location, relationship to skin creases, direction and viability of skin flaps, extent of skin loss, degree of contamination of the wound, and extent of soft tissue injury. The examiner must have a sterile field, good light, adequate exposure, and a nearly bloodless field for a thorough evaluation. The complete examination also may require an evaluation of active shoulder motion, elbow motion, and pronation and supination of the forearm and assessment of the contralateral hand.

**Figure 47-27.** Normal hand radiographs. A, Anteroposterior view. B, Lateral view. C, Oblique view. The hand is routinely examined in three different planes to identify fractures that may escape detection on the usual anteroposterior and lateral views because of overlapping bony structures. (From Rosen P, et al: Diagnostic Radiology in Emergency Medicine. St. Louis, Mosby, 1992, p 179.)
For an adequate posteroanterior view, the forearm and hand should be fully pronated so that the palm rests flat on the film. This view forms the basis for all assessments but is poor at showing fractures of the articular surface of the metacarpal head. The lateral view normally is a radiooulnar projection and is made by positioning the palm and forearm at 90 degrees to the film with the fingers splayed. This view is essential to show displacement of fracture fragments and joint dislocations. If the projection is not a true lateral view, joint dislocation, avulsion fractures, or fractures through the articular surface of the base of the phalanx may be overlooked. The oblique view is obtained with the hand and forearm pronated at 45 degrees to the film. It is particularly useful for assessing dislocation of the MCP and CMC joints and fractures at the base of the metacarpal bones. When injury is confined to the distal end of a single digit, radiologic evaluation should be limited to that digit, but the same projections are used (Fig. 47-28).

Special views are used to diagnose specific injuries. The standard views of the hand do not give true posteroanterior and lateral projections of the thumb because the plane of the thumb is at 90 degrees to that of the fingers. Separate posteroanterior and lateral views of the thumb should be requested. The posteroanterior projection of the thumb is obtained with the hand and forearm hyperpronated so that the dorsal surface of the thumb and first metacarpal rests flat on the film. The lateral view is obtained by pronating the hand and forearm to allow the lateral surface of the thumb to lie on the film. Stress views are used most often to rule out ligamentous injury to the first MCP joint. Localized widening of the joint space or subluxation may indicate a significant collateral ligament injury. Plain radiographs taken in multiple projections can help detect and localize soft tissue foreign bodies. Whether an object can be visualized will depend on its composition, configuration, size, and orientation. Many foreign bodies encountered in the ED, including almost all glass, are more dense than soft tissue and can be readily seen on plain radiographs.20

### MECHANISMS OF INJURY AND MANAGEMENT

**Trauma**

The bones of the hand are the most commonly fractured bones in the body. Radiologic evaluation of significant hand injuries is mandatory. Any hand injury that causes swelling should be evaluated radiographically with a minimum of three views. Although the classification of hand fractures is difficult and at times confusing, it generally is done according to the nature and site of the fracture line and whether the fracture is open or closed (Fig. 47-29).

A fracture is unstable if it cannot be reduced or maintained in an anatomic or near-anatomic position without fixation when the hand is placed in the “safe” or functional position. The four principal determinants of fracture stability or instability are (1) fracture configuration, (2) integrity of the periosteal sleeve and surrounding soft tissues, (3) muscle balance or imbalance, and (4) external forces.

In general, transverse fractures have a stable configuration. Spiral, oblique, and comminuted fractures are unstable. The degree of displacement also is an indicator of potential fracture instability. Fractures of inherently unstable configuration may be stable if they are nondisplaced or only minimally displaced because the periosteum is undamaged or minimally disrupted. Displacement is defined by the deformity it creates and can result in rotation, angulation, shortening, or a combination of these fractures. Although shortening has an adverse effect on muscle tension, the hand accommodates more easily to this component of deformity than to others.21

Definitive management of many hand fractures is controversial and beyond the scope of this discussion. The emphasis here is on appropriate initial interventions, including proper splinting techniques to minimize morbidity and recognizing which fractures may require operative fixation and their potential complications. Most closed injuries may be treated initially in the ED. Most open, intra-articular, periarticular, and unstable fractures require operative management by a hand surgeon.21

**Distal Phalanx Fractures**

**Pathophysiology and Clinical Features.** Fractures of the distal phalanx are the most common fractures of the hand. They occur most often as a result of crush or shearing forces, usually as a sports-related injury in children and adolescents, industrial accidents
in adults, or accidental falls in elderly persons. Distal phalangeal fractures are classified as extra-articular fractures (longitudinal, transverse, and comminuted) or intra-articular fractures. The most common location for these fractures is the distal tuft (Fig. 47-30). Because the mechanism of injury is usually direct trauma, tuft fractures often are comminuted and usually are associated with soft tissue injury to the nail, nail bed, and nail matrix. Supporting fibrous septa that radiate from the bone to contain soft tissue swelling, contributing to the severe pain that can accompany these fractures. Examination typically reveals tenderness and swelling over the distal phalanx, including the pulp.

Fractures at the base of the distal phalanx may be associated with tendon avulsion. As previously mentioned, the flexor profundus tendon attaches to the volar aspect of digits II through V, and the terminal slip of the extensor tendon attaches on the dorsal surface of the distal phalanx. In the distal phalanx of the thumb, the flexor pollicis longus inserts on the volar base, and the extensor pollicis longus inserts on the dorsal base. These tendons can avulse when subjected to excessive stress. Clinically, loss of function is evident, and small avulsion fractures along the dorsal or volar surface may be seen on radiographs. These fractures are considered intra-articular, and their management is as for other tendon injuries.

**Management.** Treatment of most fractures of the distal phalanges is directed toward the accompanying soft tissue injury. Closed tuft fractures need only symptomatic treatment with elevation (to reduce swelling) and analgesics. Fracture immobilization is rarely necessary; however, a short volar splint or hairpin splint (Fig. 47-31) is recommended for 2 to 3 days to protect the tip of the finger from further trauma and allow swelling without constriction. Immobilization should not include the PIP joint. Transverse shaft fractures with angulation or displacement may be irreducible because of interposition of soft tissue. Closed reduction may be attempted with dorsal traction on the distal fragment followed by immobilization with a volar splint and repeat radiographs for documentation of position. If this approach is unsuccessful, referral to a hand surgeon is indicated for Kirschner wire fixation.

Distal phalangeal fractures associated with nail bed laceration are considered open fractures. This may be obvious if the nail has been avulsed or torn, but recognition of nail bed laceration is more difficult in closed tuft fractures with an intact nail despite presence of a subungual hematoma. Subungual hematomas often are associated with occult lacerations of the nail bed, and in such cases, removal of the nail for accurate assessment and laceration repair uncommonly may be required.

**Complications.** Distal phalanx fractures generally are uncomplicated; however, distal phalanx fractures that appear apparently innocuous can result in prolonged morbidity, especially if associated with soft tissue crush injury. In a long-term follow-up series, DaCruz and associates showed that at 6 months 31% of tuft fractures had not healed radiographically and 70% of all patients had bothersome symptoms, including numbness, hyperesthesia, and cold sensitivity. Trauma to the nail bed may result in abnormal nail growth despite exact tissue approximation. Failure to recognize and extricate an entrapped nail bed in the fracture site may result in nonunion of the fracture. Osteomyelitis from open fractures is a rare but potentially serious complication.

**Proximal and Middle Phalangeal Fractures**

**Pathophysiology and Clinical Features.** Because the anatomy, mechanism of injury, and treatment for proximal and middle phalangeal fractures are similar, these fractures are discussed together. The proximal phalanx has no tendinous attachments. Fractures in this region have a typical volar angulation resulting from forces exerted from the extensors and the interosseous muscles. The middle phalanx has two important insertions. The tendon of the FDS divides and inserts along nearly the entire volar surface of the phalanx, and the extensor tendon inserts on the proximal dorsal base of the middle phalanx. Because of this alignment, fractures at the base of the middle
phalanx usually result in dorsal angulation, and fractures at the neck of the middle phalanx usually result in volar angulation. The mechanism of injury often determines the nature of the fracture; a direct blow is more likely to cause a transverse or comminuted fracture, whereas a twisting injury more often results in an oblique or spiral fracture. Associated injuries may include contusion or transection of digital nerves, vascular disruption, and tendon rupture.

Intra-articular fractures include condylar fractures; comminuted fractures; dorsal, volar, or lateral base fractures; fracture-dislocations; and shaft fractures involving the joint. Extra-articular fractures involve the neck, shaft, or base of the phalanx. Although most phalangeal fractures may be easily seen, condylar fractures and displaced neck fractures are not always apparent on anteroposterior radiographs; oblique views may be needed to identify them. Rotational deformities are difficult to determine by radiologic study but may appear on the lateral view as discrepancies in the diameter of the shaft at the fracture site.

Skeletal alignment can be assessed radiographically, but rotational alignment must be judged clinically by the relationship of the finger to adjacent normal fingers (Fig. 47-32). Symmetrical flexion of adjacent and normal fingers at their MCP and PIP joints is the best possible guide to accurate rotational alignment of the injured segment. Normally, all of the fingers of the closed fist except the thumb should point to the scaphoid. Alternatively, when the fingers are loosely flexed, the nails of opposing digits should lie in the same parallel plane (Fig. 47-33). The uninjured hand should be used for comparison.

Management. Similar to metacarpal fractures, phalangeal fractures require precise anatomic alignment to ensure a good result because of the intimate relationship of the flexor and extensor tendons to the phalanx. Appropriate treatment selection depends on accurate assessment of fracture stability. The angle of the fracture is an important factor in determining this stability. Transverse fractures usually are stable, whereas oblique fractures are inherently unstable. It also is important to ascertain whether the fracture has been impacted or displaced and what deforming forces are acting on it. If there is any question of the fracture’s stability, the digit should be anesthetized, and stress should be applied. Reducing phalangeal fractures usually is not necessary because approximately 75% are stable and nondisplaced. Patients with such fractures should be started on early protected motion as soon as pain subsides (within the first 3 to 5 days). Protection is provided by taping the injured digit to an adjacent normal finger, a form of dynamic splinting. This technique, known as “buddy-taping,” encourages the patient to move the finger and use the hand as normally as possible while the fracture heals (Fig. 47-34).

If the fracture is displaced or unstable, it is not suitable for dynamic splinting. In general, treatment depends on the type of trauma and the ability to achieve a stable reduction. Phalangeal fractures that are satisfactorily managed by closed reduction can be immobilized by several methods. In such cases, it is advisable to immobilize the wrist and the injured finger. Specific types of immobilization include circular cast, the Böhler method of incorporating a cast with an outrigger, gutter splints, and anterior and posterior splints (Fig. 47-35). The period of immobilization of phalangeal fractures should not exceed 3 weeks, to prevent stiffness and to minimize disability. In addition to temporary immobilization, ED management includes ice for comfort, elevation, analgesics, and referral for follow-up care. Repeat radiographs in 7 to 10 days are recommended to ensure that no delayed displacement has occurred.
Metacarpal Fractures

Metacarpal fractures generally are divided into two groups: fractures involving the first metacarpal and fractures involving metacarpals II through V. This distinction is based on the fact that the base of the thumb metacarpal is biomechanically distinct from the remaining metacarpals because of its high degree of mobility. For this reason, these two groups are discussed separately.

Metacarpal Fractures of Digits II Through V

The hand can adjust functionally to dorsal angulation in the metacarpal equal to its motion at the CMC joint, plus 10 to 15 degrees in some patients. Because the index and middle fingers are immobile at their CMC joints, they may accommodate only 10 to 15 degrees of dorsal angulation. The ring finger usually has 20 to 30 degrees of mobility at its CMC joint and may accommodate 40 to 45 degrees of dorsal angulation. The small finger generally has 30 to 50 degrees of motion at its base and may accommodate 50 to 70 degrees of dorsal angulation. Finger metacarpals may tolerate 10 to 15 degrees of lateral angulation and 3 to 4 mm of shortening. Rotational deformity, most commonly seen in spiral and oblique fractures, is poorly tolerated. A small amount of rotational deformity can translate into a substantial digital overlap when the fingers are closed to form a fist. More than 5 degrees of malrotation may cause overlapping (scissoring) of the fingers during flexion. Surgical intervention is indicated with 2 to 3 mm of shortening, 1 mm of articular surface step-off, or greater than 25% articular involvement.

Metacarpal Head Fractures

Pathophysiology. Fractures of the metacarpal head are rare. They usually occur as a result of direct trauma or crush injury and typically are comminuted. These fractures occur distal to the attachment of the collateral ligaments. Physical examination reveals tenderness and swelling over the involved MCP joint. Pain is increased if axial compression is applied along the extended digit. The presence of lacerations over the metacarpal heads is significant and suggests the possibility of an open fracture or human bite injury.

Diagnostic Strategies: Radiology. Although routine radiographic imaging of the injured hand reveals most fractures, the metacarpal heads can be difficult to assess because of overlap on the lateral view. In such cases in which clinical suspicion of a fracture exists and the initial radiographic appearance is normal, the Brewerton “ball-catcher’s” view may be helpful. This view is obtained with the digits in 65 degrees of flexion at the MCP joints and the x-ray beam angled 15 degrees radially, projecting the metacarpal heads in profile. Occasionally, com-

Unstable fractures that cannot be reduced by closed manipulation and maintained with external splinting require internal fixation. Midshaft transverse fractures tend not to be amenable to closed reduction; similarly, spiral oblique fractures and intra-articular fractures are inherently unstable and require surgical fixation if a significant portion of the articular surface is involved. Intra-articular fractures of the proximal metaphysis of the middle phalanx that have extreme comminution may require treatment in static or dynamic traction or external fixation with or without ancillary Kirschner wire fixation.

Complications. Malunion is the most common bony complication of phalangeal fractures and may result from malrotation, volar or lateral angulation, or shortening. Malrotation usually is seen after oblique or spiral fractures of the proximal and middle phalanges and may require osteotomy through the phalanx or metacarpal for correction. Volar angulation of proximal phalangeal fractures greater than 25 to 30 degrees results in pseudoclawing. This deformity makes use of the hand awkward and is esthetically unacceptable. Other potential complications include diminished motion resulting from tendon adhesions and stiffness of the PIP joint after intra-articular fractures with incongruity.

Figure 47-34. The injured finger is splinted to the adjacent normal finger. This splint provides support for the injured digit while permitting motion of the metacarpophalangeal joint and some motion at the interphalangeal joint. A piece of felt cut to the proper size is inserted between the fingers, and the two digits are taped together as shown. (From Simon RR, Koenigsknecht SJ: The hand. In Simon RR [ed]: Emergency Orthopedics: The Extremities, 3rd ed. Norwalk, Conn, Appleton & Lange, 1995, p 518.)

Figure 47-35. Gutter splints are used for the treatment of phalangeal and metacarpal fractures. A, Fractures of the ring and little fingers are immobilized in an ulnar gutter splint. B, Fractures involving the index finger and the long finger are immobilized in a radial splint. The splint is made by using plaster sheets cut to the proper size. The measurement should be from the tip of the finger to a point two thirds of the way up the forearm. (From Simon RR, Koenigsknecht SJ: The hand. In Simon RR [ed]: Emergency Orthopedics: The Extremities, 3rd ed. Norwalk, Conn, Appleton & Lange, 1995, p 519.)
Computed tomography also may be required to evaluate accurately the degree of displacement of intra-articular fractures at the MCP level.

**Management.** Emergency management of closed metacarpal head fractures consists of elevation, ice for comfort, analgesics, and immobilization of the hand in the “safe” or functional position, which balances the forces of the intrinsic muscles. In this position, shown in Figure 47-36, the wrist is extended 20 degrees, the MCP joints are flexed to 90 degrees, and the PIP and the DIP joints are extended. Referral to a hand surgeon for management and follow-up evaluation is required in all cases. Because these are intra-articular fractures, displacement by more than 1 to 2 mm predisposes the patient to a poor result; however, little consensus has been reached regarding optimal definitive treatment.30

Lacerations or puncture wounds over the dorsum of the MCP joint associated with a metacarpal head fracture should be considered open until proven otherwise. Such injuries often are caused by a clenched-fist injury and are highly contaminated wounds. Emergent consultation with a hand surgeon for operative débridement and irrigation is recommended. Prophylactic coverage with a cephalosporin is routinely recommended, although patients with highly contaminated wounds also should receive penicillin with a β-lactamase inhibitor and an aminoglycoside.31 Several studies have found preoperative wound cultures to be of no value in predicting the risk of infection or identifying the likely pathogen, and some clinicians have abandoned their use.32,33

**Complications.** Metacarpal head fractures may be associated with debilitating hand complications, including avascular necrosis, rotational malalignment, intersosseous muscle fibrosis, extensor tendon injury or fibrosis, and chronic stiffness of the MCP joint. Many of these fractures also may require late arthroplasty.25

**Metacarpal Neck Fractures**

**Pathophysiology.** Fractures of the metacarpal neck are among the most common fractures in the hand. The mechanism of injury is a direct impact force (e.g., a punch with a closed fist). A **boxer’s fracture** is a fracture of the neck of the fifth metacarpal (Fig. 47-37). Most metacarpal neck fractures have a typical apex dorsal angulation (palmar angulation of the distal fragment). They are inherently unstable because of the deforming muscle forces and frequent comminution of the volar cortex. Management generally is difficult because of this instability and the difficulty in maintaining reduction.

**Management.** For treatment purposes, metacarpal neck fractures are divided into two groups: fractures involving the ring and little finger metacarpals and fractures involving the index and long finger metacarpals. There is considerably more mobility of the metacarpals of the ring and little fingers compared with the index and long fingers. This greater mobility makes them more prone to fracture, and the relative immobility of the index and long finger metacarpals increases the need for accurate alignment after reduction. Generally, less than 15 degrees is allowed in the index and long finger metacarpals; in the ring and little finger metacarpals, 35 degrees and 45 degrees of angulation, respectively, are allowed. Any rotational malalignment must be completely corrected.

Nondisplaced ring and little finger metacarpal fractures without angulation deformity can be treated initially with ice, limb elevation, analgesia, and immobilization in a gutter splint. Nondisplaced, nonangulated metacarpal fractures of the index and long finger metacarpals are treated similarly. The splint should be in standard position of function and extend from below the elbow up to, but not including, the PIP joint. Generally, it is recommended to begin PIP and DIP motion without delay. Protected MCP motion can begin in 3 to 4 weeks.22 For isolated fractures of the little finger metacarpal neck, some clinicians advocate immediate mobilization of fractures regardless of the degree of angulation. Results with this approach include excellent function, with only minor cosmetic deformity, and early return to work. Early follow-up evaluation is advised to exclude residual angulation, rotational deformity, and delayed displacement.34

Reduction of ring and little finger metacarpal neck fractures with significant angulation or deformity may be attempted in the ED. After appropriate anesthesia is obtained, usually with a hematoma block, traction is applied on the metacarpal to disimpact the fracture. The MCP joints and IP joints are flexed at 90 degrees, and simultaneous pressure is applied in a volar direction over the metacarpal shaft and in a dorsal direc-
tion over the flexed PIP joint (Fig. 47-38). This maneuver is termed the 90-90 method and should complete reduction. A gutter splint in position of function should be applied. Postreduction radiographs should be obtained immediately and after 1 week to ensure that reduction has not been lost. If closed reduction cannot be achieved or maintained, pin fixation by a hand surgeon is necessary, and early referral is indicated.

Displaced or angulated index or long finger metacarpal neck fractures commonly require anatomic reduction and surgical fixation. ED management consists of ice, limb elevation, and the application of a volar splint. Prompt referral to a hand surgeon is mandatory.

**Complications.** Metacarpal neck fractures may have an associated rotational component that can impair function and result in overlapping of the affected finger over an adjacent finger. If excessive angulation is not corrected, the patient may experience forced hyperextension of the MCP joint and flexion of the PIP joint when extending the finger and pain when tightly grasping objects. Other complications include extensor tendon injury and collateral ligament damage. Nonunion is rare after closed metacarpal fractures.

**Metacarpal Shaft Fractures**

**Pathophysiology.** There are three types of metacarpal shaft fractures: transverse, oblique or spiral, and comminuted. Transverse and comminuted fractures usually result from a direct blow and commonly exhibit dorsal angulation (Fig. 47-39). Indirect trauma or rotational torque applied to the finger may result in a spiral shaft fracture. These fracture fragments tend to shorten and rotate rather than angulate.

**Management.** Metacarpal shaft fractures are treated differently from fractures involving the neck because rotational deformity and shortening are more likely, and less angular deformity is acceptable. In general, any rotational deformity must be corrected. Angulation deformities are unacceptable in the index and long finger metacarpals, whereas a small amount of angulation may be compensated for in the ring and little finger metacarpals. Acceptable reduction is less than 10 degrees of angulation in the former and less than 20 degrees in the latter, with less than 3 mm of shortening and normal rotational alignment.

Most metacarpal shaft fractures can be managed initially with ice, limb elevation, analgesia, and immobilization in a gutter splint. The splint should include the wrist and the entire metacarpal shaft, but not the MCP joint if the fracture is proximal to the neck. Repeat radiographic examination and referral to a hand surgeon are recommended. If manipulative reduction is necessary, operative fixation usually is indicated. Multiple displaced metacarpal shaft fractures, oblique or spiral fractures with rotational deformity, irreducible transverse fractures, and displaced open fractures will require internal fixation.

**Complications.** Complications seen in metacarpal shaft fractures are similar to the complications described for other metacarpal fractures. In addition to malrotation, which can cause a chronic painful grip, limitation of extensor function and interosseous muscle fibrosis may develop.

**Metacarpal Base Fractures**

**Clinical Features.** Fractures of the metacarpal base generally are stable and occur infrequently. They may result from either a direct blow over the base of the metacarpal or an axial force or torque applied along the digit. Examination reveals tenderness and swelling at the base of the involved metacarpal, and a significant degree of rotational deformity may be evident. Fractures at the base of the ring or little finger metacarpals may cause injury to the motor branch of the ulnar nerve, resulting in paralysis of the intrinsic hand muscles. In addition, they may be associated with a carpal bone fracture.

**Management.** Initial management in the ED consists of ice, limb elevation, analgesia, and immobilization in a bulky compressive dressing or volar splint with referral to a hand surgeon for definitive management.

**Complications.** Metacarpal base fractures may be associated with extensor or flexor tendon damage and significant rotational malalignment. Chronic CMC joint stiffness often is associated with intra-articular fractures and may necessitate arthrodesis or arthroplasty.
Thumb Metacarpal Fractures

Fractures of the thumb metacarpal are relatively uncommon because of its high degree of mobility. Although the shaft occasionally may be involved, most fractures involve the base of the metacarpal. These fractures are classified into two groups: extra-articular and intra-articular. The two common types of intra-articular fractures of the thumb are Bennett’s and Rolando’s fractures.

Extra-articular Fractures

Extra-articular fractures are seen more commonly than intra-articular fractures and usually result from direct trauma or impaction. The three types of extra-articular fractures are transverse, oblique, and epiphyseal in children. Examination reveals localized pain and swelling over the fracture site.

Mobility of the thumb metacarpal allows 20 to 30 degrees of angular deformity without functional impairment. Patients with extra-articular fractures with a greater degree of angulation should undergo closed reduction, postreduction radiographic evaluation, and immobilization of the thumb in abstraction with its IP joint extended using a thumb spica cast for 4 weeks. Transverse fractures usually are stable and can be managed with closed reduction and immobilization. If the fracture is oblique, it may require Kirschner wire fixation because of instability and a propensity for rotational deformity.

Intra-articular Fractures

Bennett’s Fracture. Bennett’s fracture is an intra-articular fracture at the base of the thumb metacarpal combined with a dislocation or subluxation of the CMC joint. The ulnar portion of the metacarpal remains in place, and the larger fragment subluxates dorsally because of the pulling force of the abductor pollicis longus and adductor pollicis muscles (Fig. 47-40). There is complete disruption of the ligaments around the CMC joint. Because stability is conferred mostly by the dorsal ligament (posterior oblique CMC ligament), dislocation ensues. The mechanism of injury usually involves an axial force acting on a partially flexed metacarpal (e.g., striking a rigid object with a closed fist). This is the most common fracture of the thumb base.

Bennett’s fracture requires an anatomic reduction. Treatment goals are to achieve stability of the CMC joint by rejoicing the volar lip fragment to the first metacarpal and to restore articular congruity. Initial management consists of immobilization in a thumb spica splint, ice, limb elevation, and analgesia. Early referral to a hand surgeon is warranted because although closed reduction can be achieved, the fragments are difficult to hold in position as a result of the pulling forces of the abductor pollicis longus and adductor pollicis muscles. Definitive treatment consists of conservative management, closed reduction with percutaneous pinning, or, if anatomic reduction fails or the fracture fragment represents greater than 20% of the articular surface, open reduction and internal fixation.

Rolando’s Fracture. Rolando’s fracture is a comminuted fracture of the base of the thumb metacarpal. Various degrees of comminution occur, but the typical configuration is in a Y- or T-shaped pattern. The severity of comminution often is underrepresented on radiographic studies. The mechanism of injury is the same as in Bennett’s fracture, but Rolando’s fracture occurs much less commonly and generally carries a much worse prognosis.

ED management of Rolando’s fracture consists of immobilization in a thumb spica splint, ice, limb elevation, analgesia, and early referral to a hand surgeon for surgical reduction. Definitive treatment is controversial and depends on the severity of comminution at the base of the thumb and the degree of displacement. If open reduction is indicated, a plate often is placed dorsally to maintain the reconstruction; with severe comminution, Kirschner wire fixation, bone graft placement, and external fixation may be used for continued distraction until healing occurs.

Complications. Complications include joint stiffness, degenerative arthritis, and malunion. Malunion is the most common late complication but usually is well tolerated at the thumb CMC joint. Posttraumatic arthritis is more common after Rolando’s fracture and may require arthrodesis or resection hemiarthroplasty. Nonunion is rare.

Pediatric Fractures of the Hand

Pathophysiology and Assessment. The hand is the most commonly injured body part in children. In young children, the most common hand fracture involves a crush injury of the fingertip with an open fracture of the distal tuft. The most distinctive feature of the immature skeleton is the presence of epiphyseal growth centers. Although the cartilaginous epiphysis is believed to be a weak link in the immature skeleton, injuries involving this region reportedly account for only 18% of pediatric fractures.

The Salter-Harris classification of epiphyseal fractures is used to direct treatment and predict outcome. The injuries are classified numerically I through V, with higher numbers corresponding to an increased risk for growth disturbance. The proximal phalanx is the most frequently fractured bone among the phalanges. The most common epiphyseal fracture in the hand is a Salter-Harris type II fracture of the proximal phalanx. It usually results from a twisting or hyperextension mechanism and most often involves the ring and little fingers and the thumb. Although lack of cooperation in this age group may make examination difficult, the clinician should look for swell-
ing, ecchymosis, and deformity. In addition, the examiner should palpate for bony tenderness and for tenderness over the collateral ligaments. Persistent limitation of motion in a young child usually implies a significant injury of the bones or joints of the digit.

Radiologic studies should be obtained and should include the same views that are obtained in an adult. In addition, comparison views may be helpful, particularly in subtle fractures. Epiphyseal fractures may be particularly difficult because they appear differently at different ages, and their varied radiographic appearance may be mistaken for a fracture.

Management. Most pediatric hand fractures can be readily treated with either simple splinting or closed reduction, followed by brief immobilization, usually for no longer than 3 weeks. A plaster or fiberglass gutter splint incorporating the adjacent uninjured finger and including the wrist is the best means of immobilizing a child’s finger fracture. The previously mentioned safe position still should be used whenever possible. Some clinicians advocate that in children, even stable injuries that ordinarily would be treated by buddy-splinting in an adult should be protected with full splinting for several weeks to prevent further injury. Open reduction and surgical fixation may be necessary for displaced intra-articular fractures, displaced Salter-Harris type III or IV fractures, and unstable fractures that cannot be maintained by closed methods.

Complications. Pediatric hand fractures heal more quickly compared with similar injuries in adults. In addition, remodeling allows correction of some step-offs or angular deformities in younger children but does not correct rotational deformities. The ability of bone to correct angular deformities by remodeling is diminished with age and cannot be relied on for adequate correction in adolescents and adults. Residual deformity is the most commonly reported complication. Other complications, including joint stiffness, tendon adherence, and non-union, are rarely seen.

Soft Tissue Injuries

Soft tissue injuries of the hand are extremely common, accounting for 82% of hand injuries seen in the ED. Trauma accounts for most of these injuries to the tendons, ligaments, and cartilage. Although such injuries are not life-threatening, they may result in potentially disabling complications, including joint laxity, loss of motion, chronic pain, swelling, and deformity.

Dislocations and Ligamentous Injuries

Ligamentous injuries to the hand are common and often missed. Injury may range from mild sprain to complete rupture and may produce various degrees of joint instability. Purely ligamentous injuries may be “tears in continuity” (grade I), partial tears (grade II), or complete tears (grade III). The disruption of joints may be complete, with the articular surfaces completely separated (a dislocation), or incomplete, leaving the articular surfaces in partial communication (a subluxation).

Because the goal of treatment is to restore functional stability, it is essential to perform a systematic evaluation of joint stability. Functionally, stability may be determined by applying gentle radial and ulnar stress to each collateral ligament and posteroanterior stress to assess volar plate integrity. Stress testing should be done in extended and moderately flexed positions to avoid the stabilizing effect of the volar plate. Comparisons with the same joint of the uninvolved hand may assist in the diagnosis. Supplemental stress radiographs also may be helpful in evaluating difficult cases.

The diagnosis of incomplete or partial ligamentous injuries is made when the joint is stable to active and passive stress but is significantly swollen, with pain elicited on stress and palpation of the involved ligament systems. The examiner should attempt to ascertain whether the most tender area is over the central slip (dorsal), collateral ligaments (radial and ulnar), or volar plate (volar). Grade I and II injuries exhibit stability with pain on stress testing. Grade III injuries show instability on stress testing. Stability of the joint provides strong evidence that optimal functional recovery would result from short-term immobilization rather than surgical intervention. Because of the three-dimensional boxlike configuration that the collateral ligaments and volar plate form around the joint, wide displacement indicates that at least two components of the ligament box complex are disrupted (Fig. 47-41). Joints with demonstrable instability should be immobilized in a gutter splint and the patient referred to a hand surgeon to determine whether surgical repair is necessary. Immobilization should be done with the IP joints splinted at 30 degrees of flexion and the MCP joints splinted at 45 to 50 degrees of flexion; when the thumb MCP is involved, it should be splinted in 30 degrees of flexion. Because the long-term effects of joint injuries are almost always joint stiffness and loss of flexion rather than persistent instability, the immobilization period usually is brief (2 to 3 weeks) and should be followed by a gradual process of active range-of-motion exercises.

Interphalangeal Joint Injuries

Distal Interphalangeal Joint. The DIP joint structure is analogous to that of the PIP joint. Additional stability is provided by the adjacent insertions of the flexor and extensor tendons, and dislocations are uncommon. Most dislocations are dorsal and usually are associated with an open wound (Fig. 47-42). Routine radiographs are used more often to rule out associated fractures than to confirm a suspected diagnosis. Treatment consists of closed reduction performed under digital or wrist block anesthesia, followed by active and passive stability testing. Reduction usually is accomplished easily by longitudinal traction and hyperextension to distract the bayonet-opposed distal phalanx followed by direct application of dorsal pressure to the base of the distal phalanx. Irreducible fractures require surgery for open reduction. The irreducibility may be due to interposition of an avulsed fracture fragment in the joint, entrapment of the profundus tendon, or buttonhole tear through the volar plate.

Figure 47-41. The collateral ligaments on either side of the joint and the volar plate form a box-like support around the joint. (From Simon RR, Koenigsknecht SJ: The hand. In Simon RR [ed]: Emergency Orthopedics: The Extremities, 3rd ed. Norwalk, Conn, Appleton & Lange, 1995.)
If the dislocation is open, the joint is contaminated, and treatment should include débridement and copious wound irrigation. The skin should be sutured and the joint splinted in slight flexion with a dorsal splint for 3 weeks. Most authorities recommend prophylactic antibiotics.

Proximal Interphalangeal Joint. Dislocations of the PIP joint are the most common ligament injuries in the hand. Stability is derived from the strong conjoined attachments of the paired collateral ligaments and the volar plate. Three types of displacement of the PIP joint may occur: dorsal, lateral, and volar. The mechanism of injury usually is sports-related, with a high-velocity blow to the end of the finger, which causes an axial load and hyperextension. Simple dorsal dislocations result when the volar plate ruptures and the middle phalanx assumes the position of bayonet opposition. Alternatively, a lateral dislocation may result from a radially or ulnarily directed force on the joint that leads to rupture of one collateral ligament and at least partial avulsion of the volar plate from the middle phalanx. In lateral dislocations, the ratio of radial-to-ulnar collateral ligament (UCL) rupture is 6:1, and the digit usually is ulnarily deviated. Volar dislocation of the PIP joint is rare. The most common mechanism of injury is a rotary longitudinal compression force on a semiflexed middle phalanx that results in unilateral disruption of a collateral ligament and partial avulsion of the volar plate. Physical examination reveals swelling and tenderness over the PIP joint and inability to extend the joint. Routine radiographs of the injured digit reveal the type of dislocation and any associated avulsion fractures.

Management. Small bone fragments at attachment sites seen on radiographs are associated with avulsions of minor ligamentous attachment points and do not indicate the need for open repair. Avulsion fractures involving 33% or more of the articular surface usually are unstable and require surgery.

Most closed dorsal and lateral PIP dislocations are treated nonoperatively. Reduction is facilitated by digital nerve block and usually can be accomplished by longitudinal traction and mild hyperextension followed by firm dorsal pressure on the proximal aspect of the middle phalanx. When reduction has been achieved, active motion is tested. Reduction is stable if no displacement occurs during active range of motion and passive stressing of the joint. More than 20 degrees of deformity and instability with lateral testing indicate a complete ligamentous injury. If stability is maintained during active range of motion, treatment consists of 3 weeks of immobilization in 20 to 30 degrees of flexion, followed by active exercises. Although stiffness, pain, and swelling are likely to persist for months, the long-term prognosis is good, and subluxation usually does not recur unless the finger is hyperextended again. If the dislocation is irreducible or there is evidence of complete ligamentous disruption with dislocation on active range of motion, operative repair is required.

The management of volar dislocations of the PIP joint is controversial. The dislocation has been described as irreducible and requiring open reduction; however, some authorities state that most volar dislocations can be reduced by a closed technique of applying gentle traction with MCP and PIP joints flexed. A stable reduction with repair of the soft tissue structures and transarticular pinning in the fully extended position also has been recommended.

Injury to the Metacarpophalangeal Joints of the Fingers

Pathophysiology. MCP dislocations are considerably less common than dislocations of the PIP joint. The MCP joints of the fingers are resistant to ligamentous injury and dislocation because of their inherent ligamentous structure, their surrounding supporting structures, and their protected position at the base of the fingers. Like the DIP and PIP joints, each MCP joint has two collateral ligaments and a volar fibrocartilaginous plate; however, the MCP joints are condyloid joints and permit, in addition to flexion and extension, 30 degrees of lateral motion while the joint is extended. Because of the shape of this articulation, the joint is more stable in flexion when the collateral ligaments are stretched than when they are in extension. They are most vulnerable to injury from forces directed ulnarily and dorsally.

Isolated injury to the collateral ligaments and volar plate of the MCP joint is rare. These injuries usually occur with hyperextension stress applied to the MCP joint with the finger extended. The patient has ecchymosis and swelling of the joint. Examination reveals tenderness along the joint and varying degrees of instability. The radiographic appearance usually is normal on routine views, but some clinicians recommend a Brewerton view to show any evidence of avulsed bone fragments. Treatment for most of these injuries consists of application of a gentle compression dressing with light plaster reinforcement and early orthopedic referral.

Dislocations of the MCP joints of the fingers are relatively rare injuries and usually are dorsal. The most common digit involved is the index finger, followed by the little finger. These dislocations result from hyperextension forces that rupture the proximal volar plate and are divided into simple and complex types. In the simple dislocation (subluxation), the joint appears to be hyperextended to 60 to 90 degrees, and the articular surfaces are in contact without interposed soft tissue. With complex (complete) dislocations, the MCP joint is in moderate hyperextension and angulated, the metacarpal head is prominent in the palm, and the distended palmar skin is dimpled. Complex dislocations have a less striking presentation but represent a more severe injury; the volar plate is interposed in the MCP joint space, and closed reduction is not possible (Fig. 47.43). Radiographic examination shows an obvious dislocation on the lateral view. Posteroanterior views reveal widening of the joint space in complex dislocations. In addition, sesamoids may be seen in the joint; this finding is pathognomonic for this injury (Fig. 47.44).

Management. After appropriate anesthesia is obtained, simple dorsal dislocations should be reduced in a way that prevents entrapment of the volar plate in the joint. Reduction is accomplished by flexing the wrist to relax the flexor tendons and applying firm pressure over the dorsum of the proximal phalanx.
PART II

Trauma / Section Three • Orthopedic Lesions

Orthopedic Lesions

Bases articulate with each other and with the distal carpal row the transverse metacarpal arch of the hand. The metacarpals are supported by strong dorsal, volar, and interosseous ligaments and are reinforced by the broad insertions of the wrist flexors and extensors (Fig. 47-45). Dislocations of the CMC joints are uncommon and often are missed. Overall, the most commonly injured CMC joint is the little finger, and most of these injuries are dorsal fracture-dislocations. The injury occurs as a result of motor vehicle collisions, falls, crushes, and closed-fist trauma.

Clinical Features and Diagnostic Strategies. Clinically the patient has swelling on the dorsum of the hand and tenderness over the involved CMC joints. Routine radiographs must be viewed carefully because fracture lines may be subtle, and the metacarpals may be obscured by superimposition. Other radiographic views that may be helpful include multiple oblique, forearm in 30-degree pronation, and Brewerton views.

Management. Initial treatment consists of ice for comfort, limb elevation, and analgesia. Closed reduction of the dorsal fracture-dislocation may be attempted after adequate regional anesthesia has been obtained. Traction and flexion with simultaneous longitudinal pressure on the metacarpal base, followed by extension of the metacarpal head when length has been restored, generally result in reduction. Even in cases in which reduction is achieved by closed means, early referral to a hand surgeon is needed because Kirschner wire fixation is advisable to ensure adequate stability. The late sequelae of fracture-dislocations include pain and weakness from traumatic arthritis secondary to imprecise alignment or chronic dislocation of the CMC joints.

Injury to the Interphalangeal Joint of the Thumb

The IP joint of the thumb is similar to a finger DIP joint except that the phalanges of the thumb typically are larger and stronger than the phalanges of the fingers. Even with the thumb’s vulnerable position, IP dislocation is uncommon. Most dislocations are dorsal, and they often are associated with open injuries. Reduction usually is simple after a median nerve block. The joint usually remains stable because the volar plate remains attached to the distal phalanx, and immobilization in mild flexion for 3 weeks usually suffices for successful management.

Injury to the Metacarpophalangeal Joint of the Thumb

The MCP joint of the thumb is a condyloid joint that allows mainly flexion and extension; however, it also permits some degree of abduction, adduction, and rotation. Its volar plate

Figure 47-43. The most important element preventing reduction in a complex metacarpophalangeal dislocation is interposition of the volar plate within the joint space (arrow). It must be extricated surgically. (From Green DP, Rowland SA: Fractures and dislocations in the hand. In Rockwood CA Jr, Green DP [eds]: Fractures in Adults. Philadelphia, JB Lippincott, 1991, p 521.)

Figure 47-44. A pathognomonic radiographic sign of complex metacarpophalangeal dislocation is the presence of a sesamoid bone in the widened joint space, indicative of interposition of the entrapped volar plate. (From DeLee JC, Drez D Jr, Miller MD: Orthopedic Sports Medicine: Principles and Practice, vol 2, 2nd ed. Philadelphia, Saunders, 2003, p 1387.)

Figure 47-45. The volar plates of four palmar metacarpals are held together firmly by the deep transverse metacarpal ligament, which is continuous with the volar plate. Eaton calls this the “intervolar plate ligament.” (From Green DP, Rowland SA: Fractures and dislocations in the hand. In Rockwood CA Jr, Green DP [eds]: Fractures in Adults. Philadelphia, JB Lippincott, 1991, p 518.)
and collateral ligaments are stronger than in other MCP joints, but its vulnerable position leads to frequent traumatic injury. Overall, injury to the MCP joint of the thumb accounts for five times the number of injuries of all other MCP joints combined.

Most dislocations of thumb MCP joints are dorsal and result from a hyperextension force that ruptures the volar plate, joint capsule, and at least part of the collateral ligament. As with other dorsal MCP dislocations, displacement ranges in extent from subluxation of the phalanx to a complex dislocation with the proximal phalanx resting over the metacarpal head. The complex dislocation is not easily reduced because of volar plate entrapment in the joint. Clinically the complex dislocation may show a dimple over the thenar eminence. Radiographic studies confirm the dorsal dislocation and reveal the sesamoids in close proximity to the proximal phalanx.

**Management.** Closed reduction may be attempted after radial and median nerve wrist block anesthesia has been obtained. Pressure is directed distally on the base of the proximal phalanx, with the metacarpal flexed and adducted. If reduction is difficult, the IP joint and wrist can be flexed to relax the entrapped flexor pollicis longus tendon. When restoration of anatomic position has been accomplished, the collateral ligaments should be tested, and reduction should be confirmed by radiographic assessment. Stability to active range of motion and stress testing suggests that immobilization in a thumb spica splint with the MCP joint in 20 degrees of flexion for 4 weeks constitutes adequate treatment. Nonreducible (complex) dislocations or dislocations with significant lateral instability require open reduction and operative repair. Hyperextension, instability, and chronic pain on pinching may occur after these injuries.

**Ulnar Collateral Ligament Injuries (Gamekeeper’s Thumb, Skier’s Thumb)**

**Pathophysiology.** Injury to the UCL was first described as an occupational hazard of Scottish gamekeepers, who damaged their thumbs by a repeated maneuver involving twisting the necks of hares. Skiing is now the most common cause of acute and chronic injury to the UCL.**Skier’s thumb** is the most common upper extremity injury in skiing and results from interference with release of the pole at the moment of impact during a fall. UCL rupture occurs 10 times more often than radial collateral ligament injury. The mechanism of injury is forced radial deviation (abduction), and the subsequent tear usually occurs at the insertion into the proximal phalanx. Stener showed that in nearly two thirds of cases of complete UCL rupture, the adductor pollicis becomes interposed between the superficial proximal portion and the deep distal portion of the ligament (see Fig. 47-45). Besides the collateral ligament injury, associated injuries of the dorsal capsule and volar plate are common.

**Clinical Features.** Physical examination reveals swelling and localized tenderness over the ulnar border of the joint and weakness of pinch. Complete and partial ruptures usually can be differentiated by clinical examination. Valgus stress testing of the UCLs is required and should be performed with the joint in full extension and in 30 degrees of flexion to avoid the stabilizing effect of the volar plate. If the examination elicits pain and guarding, the test should be done after median and radial nerve block at the wrist or with use of local infiltration anesthesia. More than 35 degrees of joint laxity or 15 degrees of laxity beyond that present in the uninjured thumb is consistent with complete UCL rupture. Routine radiographs should be obtained before the joint is stressed and may reveal a bony avulsion from the insertion of the UCL into the proximal phalanx or an associated condylar fracture. Radiographic findings of proximal phalanx volar subluxation and radial deviation may indicate complete UCL rupture because of the difficulty in diagnosing complete rupture, it is commonly misdiagnosed as a simple sprain in the ED, potentially resulting in chronic disability.

**Management.** Acute partial ruptures of the UCL can be treated effectively with a 4-week period of immobilization in a thumb spica cast; full recovery is the rule. Complete ligament tears require surgical repair because a high percentage are associated with soft tissue interposition from the adductor aponeurosis (Stener’s lesion), with limited predicted healing potential. Anatomic repair within 3 weeks of injury achieves good or excellent results in 90% of affected patients. Long-term complications include chronic pain and instability with the loss of pinch strength, which may necessitate arthrodesis.

**Radial Collateral Ligament Injuries**

Radial collateral ligament injuries of the MCP joint of the thumb are less common but equally debilitating. The usual mechanism is forced adduction with or without hyperextension. Diagnosis and treatment generally are similar to those for UCL injuries; however, anatomic differences between the two sides of the MCP joint do not permit a Stener-like lesion on the radial side, and the role of surgical repair is not well defined.

**Injuries to the Carpometacarpal Joint of the Thumb**

Injuries of the volar ligament of the thumb CMC joint, similar to those of other joints of the hand, may be complete or partial. Complete rupture permits the entire thumb metacarpal to dislocate dorsally. Controversy exists regarding the ligament most responsible for stability of the thumb CMC joint, although recent evidence implicates the dorsoradial ligament in dislocations at this joint. These dislocations are reduced easily but are unstable after reduction. Initial management consists of ice, analgesia, limb elevation, and application of a thumb spica splint. The patient should be promptly referred to a hand surgeon for possible operative repair of the ligament. If the capsule is allowed to heal with imperfect metacarpal reduction, joint instability may result, with progressive degenerative changes leading to chronic pain.

**Tendon Injuries**

Tendon injuries may involve one or more of the extensor or flexor tendons in the hand and encompass a spectrum of abnormalities, ranging from simple stretching of the fibers to complete tendon rupture with or without an associated avulsion fracture. The most common mechanisms of injury of tendons are lacerations, avulsions, and crush injuries. In a normal resting position, the fingers are flexed, with the little finger having the greatest degree of flexion and the index finger having the least. In the resting hand, a finger with a greater or lesser degree of flexion than that of the opposite hand often indicates a tendon injury. This observation may be especially useful in an uncooperative or pediatric patient. If the patient can move a joint, but active flexion or extension is limited or painful, a partial tendon laceration may be present. To assess the tendons adequately, motion should be tested against resistance. This testing may cause a partially ruptured tendon to rupture but identifies a lesion that needs surgical repair. The tendon should be placed in maximal stretch before testing to provide for the greatest strength during contraction. As a general rule, extensor injury causes greater impairment of motion than that due to a similar flexor injury. Vessels and nerves travel closely with flexor tendons, particularly in the fingers. Damage to one of these structures is likely to be associated with damage to the other two.
The position the hand was in when the injury occurred is important. When trauma occurs while the hand is held in flexion, the flexor tendons may be transected, and the distal stump would lie distal to the wound. If the hand is in the extended position, however, the tendon stumps would lie at the wound edges. When the tendons are injured by a direct blow to the hand or the fingers, the closed injury may hide significant tissue damage. Partial tendon lacerations may be associated with small surface wounds. To help exclude injury, wounds and visible tendons should be inspected while the joints are taken through a full range of motion.

Extensor Tendon Injuries

The most common site of tendon injury is the extensors over the dorsum of the hand. The extensors are predisposed to laceration because of their superficial location on the dorsum of the hand and the minimal amount of subcutaneous tissue between the tendon and overlying skin. This anatomic arrangement also predisposes the extensor mechanism to more complex tendon injuries, including abrasion, crush, and avulsion. Because the extensor tendons are not constrained in tight fibro-osseous canals except in the wrist, they also are easily located and repaired.

Injuries to the extensor tendons have been grouped into anatomic zones for easy understanding and classification. Different systems for assigning zones have been described, but the most widely accepted is that of Verdan12 (Fig. 47-46). This system defines eight zones, from zone I at the DIP joint level to zone VIII at the distal forearm level. The use of zones is convenient for assessing injury patterns, repair techniques, and rehabilitation.

Zone I Injuries

Pathophysiology. Zone I is the area over the distal phalanx and DIP joint. In this region, the conjoint extensor tendon is well defined and dorsally positioned. Injuries that occur here disrupt the terminal extensor tendon; they may be open or closed and may occur with or without a fracture. Complete laceration of the conjoint tendon results in a flexed posture of approximately 40 degrees at the DIP joint. Partial transection results in a lesser extension lag and a decrease in the strength of extension against resistance from a flexed position. The extension lag may increase if the partial injury is not treated appropriately. For this reason, exploration of dorsal lacerations near the DIP joint is important.

Mallet finger is the most common injury in zone I and refers to a closed disruption of the distal extensor apparatus.23 As a result of loss of extensor tendon continuity to the distal phalanx, there is a flexion deformity of the DIP joint. The injury can be seen in any finger but is most common in the long, ring, and little fingers. Overall, mallet finger represents the most common tendon injury in the hand seen in athletes.69 The mechanism of injury often is sudden forceful flexion of an extended finger when an object, such as a ball, strikes the tip of the finger. This mechanism is commonly encountered in athletes and often is described as “jamming” the finger. Other mechanisms include hyperextension with axial compression and direct crush injury at the DIP joint. Three types of injury patterns are recognized: type 1 tendon rupture (no fracture), type 2 tendon avulsion with a small bone fragment, and type 3 tendon avulsion with a large bone avulsion (25 to 33% of the articular surface)60 (Fig. 47-47). Fracture fragments of variable size are seen in one fourth to one third of cases (Fig. 47-48). Small avulsion fractures usually are the result of hyperflexion injuries, whereas large fracture fragments usually result from a hyperextension mechanism.60

Clinical Features. In the acute injury, clinical findings include swelling, pain, and tenderness over the DIP joint. The distal phalanx is flexed because of the unopposed action of the FDP. There is usually complete passive but incomplete active extension at the DIP joint. Although the diagnosis is easily made, the patient often seeks treatment late because the functional disability is not great.

Management. Although various treatment protocols have been proposed, splinting of the interphalangeal joint for 6 to 8 weeks has yielded good results while minimizing morbidity in a majority of patients.61 The primary goal of treatment is the maintenance of continuous DIP joint extension until tendon healing occurs. Treatment of type 1 and 2 injuries is nonoperative. Immobilization can be accomplished with either a volar or a dorsal splint made from a variety of materials, including aluminum and plastic (Fig. 47-49). The DIP joint is immobi-
lized in slight hyperextension for 6 to 8 weeks, but the PIP and MCP joints are allowed to move freely.\textsuperscript{23,62} Definitive treatment of a type 3 injury is controversial. Some authorities recommend operative repair; others recommend conservative management with uninterrupted splinting of the digit.\textsuperscript{12}

Open zone I injuries that divide the extensor tendon are treated by sutting the cut ends (Fig. 47-50). Partial and complete lacerations are repaired with either a roll suture or figure-of-eight stitch using 5-0 nonabsorbable sutures. This repair should be followed by continuous splinting of the DIP joint in full extension for a minimum of 6 weeks.

**Prognosis.** More than 80\% of patients who receive conservative treatment for mallet finger report successful outcomes; however, most patients do not regain full mobility at the DIP joint.\textsuperscript{69} Possible delayed complications include dorsal deformity, dorsal intolerance, pain, and the so-called swan neck deformity (Fig. 47-51). This abnormality develops when the lateral bands displace proximally and dorsally, resulting in increased extension forces on the PIP joint. Secondarily, the extensor lag at the DIP joint increases because the force of the FDP tendon is unopposed. The swan neck deformity occurs as a complication of a chronic untreated mallet.\textsuperscript{52}

**Zone II Injuries**

**Pathophysiology.** Zone II is the area over the middle phalanx. The central tendon is the most commonly injured structure in this zone; such injuries are the second most common closed tendon injury in athletes.\textsuperscript{59} The mechanisms for closed rupture include forced flexion of an actively extended finger, a direct blow to the dorsum of the PIP joint, and hyperextension with volar dislocation of the PIP joint. It often results from a “jamming” injury. Lacerations that occur just distal to the PIP joint also may divide the central tendon and readily extend into the joint. Wounds must be carefully explored to define the status of the PIP joint capsule.

Disruption of the central tendon causes an imbalance in the extensor mechanism. The FDS is now unopposed and flexes the PIP joint. The lateral bands displace volarly to the axis

---

**Figure 47-48.** Mallet finger fracture, lateral view. This is an intra-articular avulsion of the dorsal surface of the distal phalanx (arrow). (From Rosen P, et al: Diagnostic Radiology in Emergency Medicine. St. Louis, Mosby, 1992, p 181.)

**Figure 47-49.** Only the distal interphalangeal joint is immobilized in treating mallet fingers. This may be done with a dorsal padded aluminum splint (A), a volar unpadded aluminum splint (B), a Stack splint (C), a modified Stack splint (D), or an Abouna splint (E). Each of these splints uses a three-point (arrows) fixation principle. (From Green DP, Rowland SA: Fractures and dislocations in the hand. In Rockwood CA Jr, Green DP Jr [eds]: Fractures in Adults. Philadelphia, JB Lippincott, 1991, p 450.)
of the PIP joint and become flexors of the joint. In addition, the extensor hood retracts proximally, causing extension of the MCP and DIP joints. The resulting tendon imbalance leads to the so-called boutonnière (buttonhole) deformity, with flexion of the PIP joint and hyperextension of the DIP and MP joints (Fig. 47-52). Although open injuries of the central tendon may cause an acute boutonnière deformity, this usually is delayed several weeks after a closed athletic injury.

**Clinical Features.** Early diagnosis of a closed central tendon rupture or avulsion is difficult before the boutonnière deformity has developed. The patient typically has a history of trauma to the involved digit and a painful, swollen PIP joint. The finger is held in slight flexion at the PIP joint and slight extension at the DIP joint. Rupture of the central tendon may be differentiated from the more common injury to the collateral ligament by the location of the maximal area of tenderness on the dorsum rather than on the sides of the joint, and by the patient’s inability to extend the PIP joint actively. PIP joint extension can be tested by having the patient attempt to extend the fingers against slight resistance with the hand flat on the table and the PIP joint flexed 90 degrees over an edge of a table (the tabletop test). The radiographic appearance typically is normal but may be diagnostic if an avulsion fracture of the volar base of the middle phalanx is visualized on the lateral view.

**Management.** Patients with suspected closed central tendon injuries should be managed with splinting of the PIP joint in full extension for 5 to 6 weeks. Only the PIP joint should be immobilized, and passive and active DIP joint flexion is encouraged from the outset. Operative repair may be required for an acute closed boutonnière injury associated with a displaced avulsion fracture and injury with volar PIP joint dislocation. Early referral to a hand surgeon is advised.

When an acute boutonnière deformity is caused by an open injury, exploration of the central slip is mandatory, and a hand surgeon should be consulted. Primary repair of the tendon and Kirschner wire fixation of the PIP joint often are performed. If the joint capsule has been violated, the joint should be thoroughly débrided and irrigated, and the use of prophylactic antibiotics is recommended.

**Zone IV Injuries**

Zone IV includes the area over the proximal phalanx. The clinical findings are similar to those with zone III injury but are less severe because the PIP joint and lateral bands are intact. The resulting injury usually is partial, and the tendon ends usually do not retract appreciably. These injuries are treated with primary or delayed primary repair and appropriate splinting for 3 to 6 weeks. Simple injuries in this zone can be well approximated with 5-0 nonabsorbable sutures with buried knots. Immobilization should be done with maintenance of the wrist in extension and the MCP joints in approximately 15 degrees of flexion. Tendon adhesions are common in this zone because of associated damage to the periosteum.

**Zone V Injuries**

Zone V injuries involve the areas over the MCP joint and should be presumed to be due to a human bite until proven otherwise. These injuries occur most commonly over the MCP joints of the long and ring fingers. Radiographs are mandatory and may include Brewerton views to assess the metacarpal head closely for injury. The clinical findings with injuries to the extensor tendon at this level are flexion of the MCP joint and inability to extend the joint fully.

In an open joint injury caused by a human bite, the potential for mixed aerobic and anaerobic infections is high. Operative exploration, débridement, and irrigation are necessary. A combination of a β-lactam and a β-lactamase inhibitor drug is recommended empirically for infections related to human bites. In penicillin-allergic patients, clindamycin in combination with a fluoroquinolone may be given. The wound is left open and may be closed at 4 to 5 days if free from infection. The
resultant tendon injury usually is only a partial laceration, which may be managed with primary or delayed primary repair.

For simple lacerations at this level caused by a sharp, clean object, primary repair is indicated. The involved tendon ends do not retract and can be approximated with 4–0 nonabsorbable sutures. Sagittal bands also must be repaired if injured to prevent loss of extension or subluxation. The wrist and MCP joints should be immobilized. Early referral to a hand surgeon is advised.

Zone VI Injuries

Zone VI includes the area of the dorsum of the hand. Although these injuries may be similar in clinical appearance to zone V injuries, the joint is not involved, and these injuries generally are not as severe. Because the extensor tendons are superficial at this level, a relatively trivial-appearing skin laceration may be associated with one or more tendon lacerations. If the injury is proximal to the junctura tendineae, the patient may be able to extend the involved MCP joint because weak extensor forces are transmitted to the junctura from adjacent extensor tendons.

The tendons in this area are round or oval and easily exposed. Primary repair using a modified Kessler stitch with a 4–0 nonabsorbable material or a figure-of-eight stitch with a buried knot on the deep, palmar surface of the tendon suffices. This repair is followed by immobilization of the wrist at 30 degrees of extension and the MCP joint in neutral position. Referral to a hand surgeon for delayed primary repair also is appropriate.

Zone VII and VIII Injuries

Zone VII and VIII injuries involve the wrist and forearm. Management follows basic principles for tendon injuries.

Flexor Tendon Injuries

Pathophysiology. Flexor tendon injuries are not as common as injuries to the extensor complex and often have a subtle clinical presentation. The most common mechanism of injury is laceration, but closed traumatic disruption also may occur. FDP avulsion is the third most common tendon rupture in the hand in athletes. This injury usually is sports-related and involves a hyperextension force applied to an actively flexing digit; the classic example is that of an injured digit in a football player who grabs the clothing of an opponent who is breaking free from a tackle. Although the reason is not clearly understood, more than 75% of these injuries involve the ring finger.

Because of the closed nature of these injuries, the patient may not seek immediate care, or the condition initially may be misdiagnosed.

Clinical Features. Careful assessment is necessary to diagnose flexor tendon disruption and associated neurovascular injury. With the normal hand at rest, there is a cascade of flexion of the digits, beginning with less flexion at the index finger and progressing to more flexion toward the little finger. An injury to a flexor tendon may be evident if the involved finger does not assume a naturally flexed position. Complete disruption of the profundus tendon results in an extended position of the DIP joint as a result of unopposed extensor forces. If the FDS is completely severed, or a partial tendon injury has occurred, the digit rests in less flexion than normal. An abnormal posture of the injured digit may suggest a flexor tendon injury; this usually is confirmed by a functional examination. The FDP and the FDS should be tested separately as previously described. This examination requires careful observation: The patient may flex the distal tip with an intact profundus, but an injury to the FDS precludes flexion at the PIP joint. Disruption of the FDP tendon leads to loss of flexion at the DIP joint, instability in pinch, and loss of grip strength. Partial flexor tendon lacerations may be clinically occult. Because the tissue is torn and not lacerated, the degree of soft tissue injury and hemorrhage is greater than that seen with a laceration in the same zone. As a result, subsequent scarring within the sheath often is significant, and the adjacent superficialis tendon may become secondarily involved. Such injuries may be present if the patient complains of subjective weakness or if an abnormal position of the hand is observed at rest. Clinically, injuries are associated with pain and weakness with flexion against resistance. Despite these findings, it may not be possible to arrive at a complete and accurate diagnosis until the wound is surgically explored.

Management. Flexor tendon repairs require the expertise of a hand surgeon. Immediate or delayed primary repair is now advocated for most acute flexor tendon injuries, including avulsions of the FDP and injuries involving the so-called no man’s land, which extends from the distal palmar crease to the midportion of the middle phalanx. The advantages of primary repair with surgical reapproximation over secondary grafting for treatment of acute injuries have been well described in the literature. Relative contraindications to immediate primary repair are few and include crush wounds with poor skin coverage or tendon loss greater than 1 cm, possibly contaminated injuries over 12 hours old that cannot be converted to clean wounds (human bites are not repaired initially), the presence of inadequate pulleys, inability of the patient to cooperate, and lack of surgical experience in the necessary techniques. In such cases, a delayed primary repair can be performed 10 days after injury. Secondary repair of flexor tendons may be performed 4 weeks after injury, but repair is considered late after that. Generally, the results of primary, delayed primary, and early secondary repair are approximately equal. Treatment of partial flexor tendon lacerations is controversial, but referral to a hand surgeon for further exploration and possible repair is prudent.

If a hand surgeon is not immediately available, open wounds should be copiously irrigated and closed with 5–0 nylon and the hand splinted with the wrist in 30 degrees of flexion—the MCP joints flexed approximately 70 degrees and the IP joint flexed 10 to 15 degrees. This flexion ensures that no further damage occurs to the tendon and that the tendon will not contract further on movement. The patient also should receive tetanus immunization as indicated, and most authorities recommend empirical use of broad-spectrum antibiotics. Most closed tendon injuries require referral to a hand surgeon because of the risk of long-term disability.

Complications. With optimal management, most patients with flexor tendon injuries have good to excellent outcomes. With injuries involving the no man’s land, results may be poor, and tendon grafting occasionally is required. Overall, adhesions remain the most significant problem after operative repair. Other complications include triggering, bowstringing, and intratendinous epidermoid cyst formation.

Mutilating Injuries

Mutilating injuries to the hand are encountered frequently in the ED. These are severe multistructural injuries that destroy
Fingertip Injuries

Fingertip injuries may involve any structures distal to the DIP joint, including the skin, volar pulp tissue, distal phalanx, nail, nail bed, and related structures. These are among the most common injuries of the upper extremity and, although usually minor, may have significant long-term consequences. The goals of management are to maintain finger length and to achieve good tissue coverage, near-normal sensibility, and early functional recovery.

Fingertip Amputations

Classification. Fingertip amputations are the most common type of amputation of the upper extremity. In zone I injuries (Fig. 47-53), the proximal two thirds of the nail bed is preserved. In zone II injuries, bone is exposed, and in zone III injuries, the entire nail bed is lost. Radiographic studies are indicated if bony avulsion injury or fracture cannot be excluded. Most of these fingertip injuries can be managed on an outpatient basis.

Management. Treatment of distal fingertip injuries is controversial; consequently, management must be individualized, and few guidelines are available. Generally, most hand surgeons try to maintain length of the thumb by whatever means possible. The index finger is considered next before the other fingers. An intact pulp-to-pulp pinch mechanism is the principal goal. Other factors to consider include the patient’s age, health, occupation, and handedness.

In most fingertip amputations distal to the DIP joint, adequate care can be provided with conservative wound management. The simplest and most often best method for managing a fingertip amputation is allowing the wound to heal by secondary intention. This method generally is effective and produces good results if the wound is less than 1 cm. Large dorsal wounds also heal well by this method. It is the treatment of choice in childhood fingertip amputations, particularly when no bone is exposed. In cases in which a small protuberance of phalangeal bone (extending no more than 0.5 cm) is exposed, it may be trimmed back with a rongeur to just below skin level and the wound allowed to heal by secondary intention; if the bone is left exposed without soft tissue coverage, the patient will need an operative procedure. In most cases, the wound heals through a process of granulation, wound contractions, and reepithelialization within a few weeks. Initial management should include careful and meticulous wound cleansing, a nonadherent dressing, appropriate tetanus prophylaxis, and splinting to protect the tip. Amputations that involve the distal phalanx usually are treated as contaminated open fractures with an initial intravenous dose of a cephalosporin followed by an oral course. Patients should have appropriate follow-up care to ensure adequate healing and recovery.

Management of fingertip injuries involving significant soft tissue (especially volar) or bone loss usually requires the expertise of a hand surgeon. Surgical management may include primary closure, full-thickness or partial-thickness skin grafts, composite grafts, adjacent flaps, regional flaps from the hand, distant flaps, and reimplantation. With most of these operative techniques, repair is best performed as a primary procedure under ideal circumstances or as a delayed procedure when necessary. A flap may be used to cover exposed bone or soft tissue avulsion and to add bulk to the tip. The nail bed tissues should be preserved because the presence of a nail affects the cosmetic result. At least 5 mm of healthy nail bed distal to the lunula is needed for nail adherence. Skin grafting is a common method for treating fingertip amputations with significant avulsed tissue and can provide a functional and anesthetic reconstruction.

Complications. These injuries commonly leave the patient with a painful, cold-intolerant fingertip; this complication has been described after primary closure, coverage with grafts or flaps, and healing by secondary intention. Skin grafting may result in induration, fissuring, and diminished sensibility. Nail deformity is common, particularly with considerable volar loss of tissue.

Acute Nail Bed Injuries

Injuries of the nail bed most commonly result from localized trauma to the nail with subsequent compression of the nail bed. The most common type of injury is the simple laceration followed by stellate laceration, crush, and avulsion. The middle and distal thirds of the nail bed are the most common sites of injury, and 50% of these injuries involve fractures of the distal phalanx or tuft. Radiographs are required in most cases to show occult fractures and foreign bodies.

Subungual Hematoma

Subungual hematomas result from crush injury or blunt trauma to the nail bed with bleeding from the rich vascular bed. The nail bed is predisposed to injury because it is interposed between the firm nail and the distal phalanx. The injury is manifested by pain and dark red to black discoloration of the nail bed and is classified by the percentage of area beneath the

Figure 47-53. Classification of nail bed and fingernail injuries: zone I, distal to the bony phalanx; zone II, distal to lunula (between distal end of lunula and end of phalanx); zone III, proximal to distal end of lunula. (From Rosenthal EA: Treatment of fingertip and nail bed injuries. Orthop Clin North Am 14:675, 1983.)
nail that is involved. When the fingertip is unstable or the mechanism of injury suggests a significant distal phalanx fracture, a radiograph should be obtained to identify associated fracture.

Management. Small subungual hematomas do not require drainage; the blood is incorporated into the nail and eventually removed with the free edge. Large hematomas cause significant discomfort and should be removed by nail trephination with a heated paper clip or a hot microcautery unit. Some clinicians recommend a surgical scrub of the finger before perforation of the nail to prevent contamination of the subungual area and the subsequent risk of infection and potential osteomyelitis, but this generally is unnecessary. Anesthesia is not necessary, and pain relief is immediate with decompression. If a significant fracture is present, the digit should be splinted. Although a distal phalangeal fracture with a subungual hemATOMA is technically an open fracture, such injuries usually heal without problems. Ungual tuft fractures are not associated with osteomyelitis. The risk of infection with an open fracture of the phalanx proper must be considered, and a broad-spectrum antibiotic and close follow-up monitoring are recommended. Patients with significant hematomas should be informed that they may lose the nail.

Some authorities recommend nail removal and nail bed repair if the size of the subungual hematoma is greater than 50% of the nail area. Simon and Wolgin \(^{77}\) attempted to correlate the association between subungual hematoma size, digital phalanx fractures, and occult nail bed lacerations. In their series, patients with a subungual hematoma greater than half the size of the nail had a 60% incidence of nail bed laceration requiring repair, and if an associated fracture of the distal phalanx was present, the incidence was 95%. If more than 25% to 50% of the visible portion of the nail is undermined by hematoma, many clinicians recommend removal of the nail, inspection of the nail bed, and repair of injuries. \(^{78-80}\) However, several studies have found no notable differences in outcome between nail trephination alone and formal nail bed repair regardless of hematoma size in cases with an intact nail and nail margins. \(^{78-80}\) As a result, many authorities now recommend nail removal and repair of the nail bed only if the nail is broken or the nail edges are disrupted. \(^{75}\)

Nail Bed Lacerations

Lacerations of the nail bed should be repaired to minimize esthetic deformity and the duration of functional impairment. These injuries generally do well after primary repair, but late reconstruction of the nail bed is unpredictable, and usually little improvement is obtained.

Simple and crushing lacerations should be repaired accurately with 5–0 or 6–0 absorbable suture, ideally under loupe magnification. The results with both injuries should be satisfactory in more than 90% of cases. \(^{80}\) After the nail bed is accurately approximated, a hole is burned through the nail to allow drainage of blood from the subungual area after the nail is reinserted into the nail fold. The avulsed nail may be sutured in place or secured with tape. A single thickness of nail is reinserted into the nail fold. The avulsed nail may be removed with the free edge. Large hematomas cause sufficient to penetrate skin from a distance, and contact of the hand is not a prerequisite for injury to occur. High-pressure injection injuries to the hand are uncommon, and most are occupation-related. The usual cause is an accident involving industrial equipment, with machinery such as grease guns, spray guns, and diesel engine injectors accounting for most of these injuries. \(^{85}\) A wide variety of materials, including paint, paint thinner, grease, oil, hydraulic fluid, plastic, wax, water, and semifluid cement, have been reported to be injected. Generally, substances that are highly viscous (e.g., grease) require higher forces to produce injury than those from paint, oil, and solvents. The high pressures involved are sufficient to penetrate skin from a distance, and contact of the device with the hand is not a prerequisite for injury to occur. High-pressure injection injuries have been associated with amputation rates as high as 60 to 80%. \(^{84}\) Recent data suggest amputation rates of 30%, which may be due to higher vigilance and recognition of early tissue injury. \(^{85}\) Early recognition and intervention are essential. Even with early intervention, the injury leads to significant impairment. Amputation is more likely if débridement is delayed more than 6 hours. \(^{84}\)

Pathophysiology. Patient characteristics and injury circumstances often are similar in high-pressure injection injuries. The patient generally has a history of coming into close

proximity to the jet stream during cleaning of the nozzle or testing or operation of the equipment. The patient usually is an inexperienced worker, and the nondominant hand most commonly is involved, with the index finger the most common site.

Tissue injury from high-pressure injection generally depends on physical, chemical, and biologic factors. Of particular importance are the type, amount, and velocity of injected material and the anatomic location of the injury. The most important factor is the type of material injected, which determines the likely tissue inflammatory response and the resulting fibrosis that develops during healing. Paint and paint thinner produce a large, early inflammatory response, resulting in a high percentage of amputations. By contrast, grease injuries cause a small inflammatory response and carry a lower amputation rate but are associated with oleogranuloma and fistula formation, scarring, and loss of digit function. The amount of material injected into the confined space of the digits or palm determines the degree of mechanical distention and the potential for vascular compromise. The velocity of the injected material and the site of tissue penetration determine dispersion, which may include the digit, hand, and forearm. Injection injuries to the palm and thumb produce less tissue loss than that from injections of the fingers.

Clinical Features. The patient who seeks treatment early after injury may have minimal symptoms with either an innocuous entrance wound or no visible break in the skin. Fusiform swelling resulting from mechanical distention of the tissue by the injectant usually is apparent. Several hours later, the involved digit or palm becomes extremely painful, swollen, and pale because of vascular compromise and tissue necrosis. Careful examination is necessary to document the extent of injury and associated neurovascular function. Radiographs of the involved hand can help determine the spread of material and the amount of débridement necessary, because certain injected materials are radiopaque. In addition, they may reveal subcutaneous emphysema.

Management. Initial ED management includes splinting, elevation of the affected limb, tetanus prophylaxis, analgesia, and broad-spectrum antibiotics. Digital blocks are contraindicated because of the potential for increased tissue pressure, which may aggravate vascular compromise. Urgent hand surgery consultation is warranted because most cases require early extensive surgical decompression and débridement. The keystone in treatment of these injuries is prompt recognition of the severe nature of the injury and aggressive early débridement. Current treatment methods using irrigation and wide débridement have significantly reduced the amputation rate.

Complications. Early recognition and treatment, including operative decompression and débridement, greatly influence outcome. Early surgical amputation should be considered in cases in which the affected digit is initially cool or poorly perfused. In most other cases, joint stiffness is a late sequela.

Amputations and Ring Avulsion Injuries

Few epidemiologic studies have been done on amputation injuries. Traumatic amputations have been reported to constitute 0.1 to 1% of all hand injuries. Amputation may be complete or partial. Injuries with interconnecting tissue between the distal and the proximal portions are considered incomplete, or partial, amputations. Complete amputations will necessitate replantation, whereas with partial amputations, revascularization is attempted. Traumatic amputations most commonly result from local crush injuries and occur infrequently from a sharp guillotine mechanism. Partial and complete amputations reportedly occur with equal frequency. The former are often related to the use of power saws and lawn mowers.

Ring avulsions include a spectrum of injuries from partial degloving of the skin of a finger to loss of the entire digit and entire length of a flexor tendon. These injuries usually occur when a ring on a finger catches on an object during a fall. In addition to neurologic and arterial injuries, there may be complete disruption of the venous return of the finger. Generally, these injuries represent complex management problems, and treatment may range from primary amputation to microvascular repair with reimplantation and free tissue transfer in addition to local flap, pedicle flap, or graft coverage.

The initial care and treatment for the patient who has had a body part amputated are the same as for any trauma patient. After the initial primary assessment and stabilization of the patient, the injured extremity should be examined carefully with documentation of neurologic, vascular, and musculotendinous function. Subsequent care should be directed toward preservation of the limb and its components. General management goals include the following: (1) provide supportive care, such as control of hemorrhage with direct pressure and elevation; (2) prolong the time that the amputated tissues remain viable; (3) protect wounds from further injury; and (4) arrange expeditious consultation by a surgical subspecialist. With few exceptions, all completely amputated parts should be considered for reimplantation, and all partially amputated parts should be considered for revascularization.

In complete amputations, the proximal stump and the amputated part should be examined for degree of tissue injury, contamination, and associated injuries. Gross contaminants can be removed by irrigation with normal saline. Local antiseptics, especially hydrogen peroxide or alcohol, should not be used because they may damage viable tissues. The wound should not be manipulated, clamped, tagged, or traumatized further in any way. The stump should be covered with a saline-moistened sterile dressing to prevent further contamination and desiccation and the limb elevated to help reduce edema and control bleeding. The amputated part requires minimal handling and should be cooled as soon as possible. After being wrapped in saline-moistened gauze, the part is sealed in a dry plastic bag, which is placed in ice water. Ice should not come in direct contact with the tissue because this can cause local damage. Amputated parts should not be discarded or sent to the pathology department because even if they cannot be replanted, they may serve as a donor source for skin, bone, or vessel grafts. Radiographs of the amputated part and proximal stump should be obtained. The use of analgesic medications may be necessary, and appropriate tetanus prophylaxis can be administered. The use of prophylactic antibiotics is indicated in amputation injuries because significant devitalized tissue often is present. Most authorities recommend empirical coverage for S. aureus with a combination of penicillin G and an antistaphylococcal antibiotic or first-generation cephalosporin.

Treatment for partial amputations with vascular compromise is the same as that just described. The wound should be cleaned with normal saline irrigation, and the injured part wrapped in a sterile moist dressing and splinted to protect it from further injury. Cold packs are applied to the dressings to prevent warm ischemia.

The time for which an amputated part can survive before reimplantation has not been determined. As a general rule, the more proximal the amputation, the less ischemia time the amputated part can tolerate. Attempts to extend viability during ischemia have shown that the most important controllable factor is the temperature of the amputated part.

Vascular Injuries

BOX 47-2

CLASSIC INDICATIONS FOR AND CONTRAINDICATIONS

TO REPLANTATION

Indications

■ Multiple digits
■ Thumb
■ Wrist and forearm
■ Sharp amputations with minimal to moderate avulsion
  proximal to the elbow
■ Single digits amputated between proximal
  interphalangeal joint and distal interphalangeal joint
  (distal to flexor digitorum superficialis insertion)
■ All pediatric amputations

Contraindications

■ Amputations in unstable patients secondary to other
  life-threatening injuries
■ Multiple-level amputations
■ Self-inflicted amputations
■ Single-digit amputations proximal to the flexor
digitorum superficialis insertion
■ Serious underlying disease, such as vascular disease,
  complicated diabetes mellitus, or congestive heart
  failure
■ Extremes of age

ischemia may be tolerated for 6 to 8 hours; cooling the part to

4° C extends this time to approximately 12 to 24 hours with
distal amputations. Successful reimplantation of digits after 40
hours of warm ischemia has been reported. The decision of whether to attempt reimplantation should

be made by the surgeon who is responsible for performing the

procedure. On occasion, final judgment regarding replantation

may be delayed until after microscopic inspection of vessels

and nerves has been completed. Patient selection generally

is based on the nature and level of the injury and patient age

and health-related factors. The classic indications for and con-

traindications to replantation are listed in Box 47-2. The

thumb is needed to preserve the function of opposition, and

all such traumatic amputations should be considered for micro-

vascular salvage regardless of the level of amputation or mech-

anism of injury. Loss of the thumb is equivalent to a 40% loss

of function of the hand. Similarly, all amputations in children

should be considered for replantation. In reimplantation of
digits amputated distal to the insertion of the FDS between
the PIP joint and the DIP joint, good motor and sensory func-
tion often is achieved. If the amputated part is crushed,
mangled, or amputated at multiple levels, however, replan-
tation usually is contraindicated. With digits that cannot be
replanted, skin coverage by flaps or ray resection will be
required.

Complications. Replanted fingers and hands never regain pre-
morbid function. Replanted and revascularized parts may
develop cold intolerance, stiffness, loss of sensation, pain, mal-
unions, and nonunions. Even successful reimplantations may
require repeated operative procedures and involve prolonged
disability. Necrosis is an obvious sign of failure.

Vascular Injuries

Significant vascular disorders of the hand are uncommon com-
pared with other problems of the hand. The vascular supply
to the hand and digits is duplicated so that isolated arterial
injuries to either side seldom result in ischemia. Lacerations

of the arteries of the hand may stop bleeding by the time the
patient is evaluated; in these situations, a history of pulsatile
bleeding is highly suggestive of an arterial injury. Although
most arterial injuries are the result of penetrating trauma,
blunt trauma to the hand occasionally can result in arterial
thrombosis or a false aneurysm. In addition, associated inju-
ries should not be overlooked. Because digital nerves invari-
ably cross with and are superficial to the digital artery, an
arterial lesion should raise the possibility of an accompanying
nerve injury.

Circulatory status is assessed as previously described by
observation for cyanosis or pallor, palpation of radial or ulnar
pulses at the wrist, assessment of capillary refill, and the use
of Allen’s test. Ischemic pain is the most common initial com-
plaint of patients with vascular insufficiency, along with physi-
ical manifestations of pallor and gangrene. The presence of a
mass, with or without pain and tenderness, is the second most
common initial complaint.

Management. Lacerations or amputations of the upper limb
rarely cause life-threatening hemorrhage. Even a major vessel
that is completely transected usually retracts, constricts, and
cLOTS. Major vessels often continue to bleed briskly, however,
from partial transections with life-threatening hemorrhage.
Usually, hemorrhage can be adequately controlled with direct
pressure and limb elevation. If necessary, a proximally placed
blood pressure cuff inflated to 30 mm Hg above systolic pres-
sure can be used for short periods (less than 30 minutes) to
to control severe bleeding. Vascular clamps and hemostats should
not be used in the ED to control bleeding in the hand because
of the danger of inadvertently crushing nerves and tendons.
Lacerated arteries should be repaired if symptoms of ischemia
or an associated nerve injury are present. Arterial repair is
not mandatory in isolated arterial injuries with good distal
vascularity because there is a high rate of thrombosis after
reanastomosis. If the decision is made not to repair a lacerated
artery, both stumps should be ligated to prevent further bleed-
ing. Palmar arch lacerations may be difficult to visualize in
the ED and usually require surgical exploration to control
bleeding.

Compartment Syndrome in the Hand

A compartment syndrome develops when elevated pressure
within a closed fascial space reduces perfusion to the point of
muscle and nerve dysfunction. In the hand, 10 compartments
are evident on cross section through the palm (Fig. 47-54). In

Figure 47-54. Cross section through the palm showing structures
involved in forming the compartments of the hand. (From Rowland SA:
Fasciotomy: The treatment of compartment syndrome. In Green DP [ed]:
p 670.)
addition, the fingers are compartmentalized by fascia and skin at flexor creases. Because these compartments are not interconnected, each additional compartment must be surgically decompressed if muscle ischemia is suspected.95,96

Nerve Injuries

Nerve injuries may result from a direct blow, puncture or laceration, crush injury, injection injury, or amputation. These injuries are divided into three main groups: neurapraxia, axonotmesis, and neurotmesis. In neurapraxia, there is loss of function of the nerve, but the axon, Schwann’s sheath, and endoneurium remain intact. Recovery in these cases is usually complete within days. In axonotmesis, the axon is severed within an intact endoneurial tube. The distal axon degenerates and is absorbed after disruption. The proximal portion of the severed axonal stump can regenerate along the intact endoneurial tube at a rate of approximately 1 to 3 mm/day. Neurotmesis refers to complete disruption of all nerve elements. Regrowth of the proximal axonal endings does not occur along the endoneurial tubes, unless the severed nerve endings are reapproximated.97

Peripheral nerve injuries are diagnosed by physical examination showing loss of motor or sensory function. Specific nerves at risk should be examined as previously outlined. Injury most commonly involves one of the digital nerves but also may be localized to the median, radial, or ulnar nerve.38

Management. Identification of the injury and appropriate referral are important aspects in the initial management of patients with nerve injuries in the hand. Patients with closed nerve injuries not associated with compartment syndromes should be referred to a hand specialist for serial examinations. All digits that have lost function as a result of a nerve injury should be splinted to prevent further inadvertent injury. If function does not return within 3 weeks, electromyograms and nerve conduction studies can help differentiate neurotmesis from axonotmesis and determine the need for surgical exploration.97,98

Lacerated nerves require reapproximation by hand surgeons. In general, all motor branches of the ulnar and median nerves should be repaired. Additionally, digital nerve injuries proximal to the DIP crease on the radial aspect of the index finger, the ulnar aspect of the little finger, and both sides of the thumb should be considered for repair.54 Clean, single-nerve lacerations should be repaired primarily when feasible. Complex nerve injuries may involve wound contamination or extensive tissue damage and usually are managed by delayed repair to allow for improved soft tissue conditions. Although the functional recovery is never complete, a good outcome can result from primary and delayed repair. In general, sensory recovery returns more often than does motor function.

Complications. Complications of nerve injuries include motor and sensory loss, atrophy from denervation, chronic paresthesias, regrowth of painful neuromas, and sympathetic dystrophy.

Infections of the Hand

The unique anatomic structures of the hand affect the nature of infections in this region of the body. In general, hand infections can be divided into infections involving the skin, subcutaneous tissues, fascial spaces, tendon, joint, and bone. Fibrous compartments of the distal fingertips contain the spread of infection, whereas flexor tendon sheaths allow infection to travel considerable distances along the lengths of the tendons from the original site. Infections in the deep spaces of the palm usually manifest on the dorsal surface of the hand.

Figure 47-55. Drainage of paronychia. A, Eponychial fold is elevated from the nail for a simple paronychia. B, Lateral nail is removed if pus tracks under it. A small eponychial incision may be necessary. C, Proximal nail is removed if pus tracks under it. Two incisions are needed to remove the proximal nail. (From Moran GJ, Talan DA: Hand infections. Emerg Med Clin North Am 11:601, 1993.)
Pathophysiology. A felon is an infection of the pulp of the distal finger or thumb. It differs from other types of subcutaneous abscesses because of the presence of multiple vertical septa that divide the pulp into small fascial compartments. The usual cause is penetrating trauma with secondary bacterial invasion. The most common pathogen is *S. aureus*, although gram-negative organisms and polymicrobial infections also have been described. Although the septa may facilitate an infection in the pulp and inhibit drainage after incomplete surgical decompression, they provide a barrier that protects the joint space and the tendon sheath by limiting the proximal spread of infection. Clinically a felon begins as an area of cellulitis and inflammation that progresses rapidly to severe throbbing, pain, swelling, and increased pressure in the distal pulp space.

Management. Traditional management of felons emphasizes the need for early and complete incision through the sepsa to provide adequate drainage and to relieve pressure in septal compartments. Most felons can be drained by a single lateral incision. The incision should be made along the ulnar aspect of digits II to IV and the radial aspects of digits I and V, avoiding pincher surfaces. The incision is begun approximately 0.5 cm distal to the DIP joint crease and dorsal to the neurovascular bundle of the fingertip. The incision is extended to the free edge of the nail (Fig. 47-56). The wound should be irrigated and loosely packed with gauze, and the affected finger splinted. The packing is removed in 48 to 72 hours, and the wound is left to close secondarily. Most felons are treated empirically with an antistaphylococcal oral antibiotic for at least 5 days pending culture results. Some authorities recommend draining this abscess where it “points,” using a volar midline incision that does not cross the distal flexion crease.

Complications. If untreated, the expanding abscess can extend toward the phalanx, producing an osteitis or osteomyelitis, or toward the skin, resulting in necrosis and formation of a sinus tract on the palmar surface of the digital pulp. Other complications include soft tissue and bony tuft necrosis, osteomyelitis, septic arthritis of the DIP joint, and flexor tenosynovitis from proximal extension. The lateral incision used to drain felons commonly leaves unstable finger pads or may result in painful neuromas or anesthetic fingertips. “Fishmouth” incisions may destroy the blood supply to the fingertip. Longitudinal midline incisions on the volar surface may leave scars over an important area for sensation but do not have the other disadvantages of lateral incisions. Any incision that is made too deeply and proximally can injure the flexor tendon sheath, initiating a tenosynovitis.

Herpetic Whitlow

Epidemiology and Pathophysiology. Herpetic whitlow is a self-limited herpes simplex viral infection of the distal finger. It is the most common viral infection of the hand. Infection by human herpes simplex virus type 1 or 2 is clinically indistinguishable. Direct inoculation of the virus into an open wound or broken skin is the usual mechanism of primary infection. Herpetic whitlow commonly is reported in adult women with genital herpes and children with coexistent herpetic gingivostomatitis. Health care workers are at increased risk for development of this infection as an occupational hazard secondary to exposure to orotracheal secretions; however, a review of herpes infections in the hand found that only 14% of adult cases occur in health care workers. The overall incidence has decreased, probably as a result of heightened awareness of the condition and strict infection control precautions.

Clinical Features. The infection usually involves a single finger and begins with localized pain, pruritus, and swelling, followed by the appearance of clear vesicles. Systemic symptoms usually are absent; however, secondary infection of the vesicles can occur. More typically, the vesicles coalesce over 2 weeks to form an ulcer, which may develop a hemorrhagic base. At this stage, it may be difficult to distinguish herpes simplex infection of the hand from more common bacterial infections, such as felon or paronychia. The distinction is important because drainage of the herpetic lesions is contraindicated and may lead to viral dissemination and secondary bacterial infection. A careful history is important to determine risk of a possible herpetic etiology. On examination, tenderness is present but is noticeably less than that typical for bacterial infections. In addition, the pulp space remains soft and does not become tense, as it does in a bacterial felon.

Diagnostic Strategies. The diagnosis usually is made clinically on the basis of the appearance of the lesion and the history of recurrence or potential sources of inoculation. The diagnosis may be confirmed by viral culture or a Tzanck smear showing multinucleated giant cells in a scraping taken from the base of an unroofed vesicle.

Management. Herpetic whitlow usually resolves spontaneously in 3 to 4 weeks, although recurrence is common, occurring in up to 20% of cases. The main goals of treatment are to prevent oral inoculation or transmission of the infection and to provide symptomatic relief. The involved digit should be kept covered with a dry dressing. Oral acyclovir has a role in treatment for immunocompromised patients and patients with frequently recurring infections, but its role in nonimmunocompromised patients is less clear. Topical acyclovir has not been shown to be effective in either the treatment or the prophylaxis of this disorder.

Tenosynovitis

Pathophysiology. Acute synovial space infections in the hand usually involve the flexor tendon sheaths and the radial and ulnar bursae. The tendon sheaths are double-walled, with a visceral layer adherent to the tendon and a parietal layer extending from the midpalmar crease to just proximal to the DIP joint. The flexor tendon sheath of the thumb is continuous with the radial bursa of the palm, and the small finger...
sheath is continuous with the ulnar palmar bursae. The ulnar bursa surrounds the superficial and deep flexor tendons, and the radial bursa surrounds the flexor pollicis longus. These two bursae communicate in 80% of persons; in most instances, however, the tenosynovial coverings of digits II, III, and IV do not communicate. Infections in the synovial spaces in the hand tend to spread along the course of the flexor tendon sheaths and may spread to the midpalmar, thenar, and lumbrical compartments. Infections usually are caused by penetrating trauma to the sheath, but they occasionally result from hematogenous spread. The most commonly isolated organisms are S. aureus and streptococci, followed by gram-negative organisms and enterococci.¹⁰⁶

**Clinical Features.** Four cardinal signs of acute flexor tenosynovitis usually are present and help differentiate tenosynovitis from other soft tissue infections in the hand: (1) tenderness along the course of the flexor tendon, (2) symmetrical swelling of the finger, (3) pain on passive extension, and (4) a flexed posture of the finger.¹⁴ All four signs may not be present early in the course of infection. The third sign may be the most important. Early recognition and treatment are essential because elevated pressure within the enclosure of the flexor tendon sheath can occlude the already tenuous circulation to the tendon, resulting in necrosis and proximal spread.

**Management.** All patients with flexor tenosynovitis require hospital admission and prompt consultation with a hand surgeon to determine whether open drainage or closed tendon sheath irrigation is indicated. In early cases or uncertain diagnoses, the hand should be splinted in a bulky dressing and elevated, and intravenous antibiotics should be initiated. Infections secondary to penetrating trauma should be treated with a penicillinase-resistant antistaphylococcal penicillin or first-generation cephalosporin. Disseminated gonorrhea must be considered in all sexually active persons, especially if a traumatic cause for the infection is not apparent. In such cases, some authorities recommend empirical treatment with ceftriaxone until results of final cultures (including mucosal sites) are available.¹⁰⁷,¹⁰⁸ Surgical treatment is indicated for established cases or when improvement is not evident within 24 hours.

**Deep Space Infections**

**Anatomy and Pathophysiology.** The deep fascial or palmar spaces of the hand include the midpalmar space, the hypothenar space, and the thenar space. Three additional, more superficial spaces of the hand are the dorsal subcutaneous space, the dorsal subaponeurotic space, and the interdigital web space.¹⁰⁹ (Fig. 47-57). Although anatomically distinct from the deep spaces owing to their lack of well-defined anatomic borders, superficial spaces can harbor infections that present similarly to deep space infections.¹⁰⁹ The fascial spaces are potential rather than actual spaces in a normal hand.¹¹⁰ These closed compartments are susceptible to infection from direct penetrating trauma, infection in contiguous compartments, or hematogenous seeding. The most commonly isolated pathogens are S. aureus, streptococci, and coliforms.

**Clinical Features.** The unique anatomic features of the deep fascial spaces lead to characteristic clinical findings when these regions are involved with pyogenic infection. The dorsal subaponeurotic abscess causes swelling and erythema on the dorsum of the hand. Pain with passive movement of the extensor tendons often is present, but it may be difficult to distinguish clinically from simple cellulitis on the dorsum of the hand. Subfascial web space infections commonly result when palmar blisters become secondarily infected. The infection tends to spread dorsally into the interdigital space and produce a characteristic hourglass configuration, or the so-called collar-button abscess (Fig. 47-58). Thenar space infections are characterized by pain and swelling of the thenar eminence and the first web space; the thumb is held in abducted and flexed position.¹¹⁰ In midpalmar infections, clinical features include loss of the normal hand concavity and tenderness of the central palm; movement of digits III and IV is painful. Suppurative tenosynovitis of the second digit can rupture proximally into the thenar space, with subsequent abscess formation. Tenosynovitis of digits III, IV, and V may be responsible for a midpalmar space infection.

**Management.** Treatment of all deep fascial space infections involves intravenous antibiotics and operative exploration and drainage by experienced surgeons. The most common practice is to use broad-spectrum empirical coverage with a β-lactamase-resistant penicillin or a first-generation cephalosporin.
Septic Arthritis

Pathophysiology. Septic arthritis in the hand may involve the IP, MCP, CMC, or radiocarpal joints. These joints usually are infected by direct inoculation of bacteria from penetrating trauma or by spread from contiguous infective process, such as a felon or tenosynovitis. Hematogenous spread may occur but is less common than in other joints of the body. S. aureus is the most common cause; streptococci, Haemophilus influenzae, Pseudomonas aeruginosa, and coliforms are involved much less commonly.110 A survey at a large county hospital found that the most common isolated organisms were staphylococci and streptococci in nearly equal numbers, with enterococcus, corynebacterium, and anaerobes encountered rarely.110-112 Monarticular nontraumatic septic arthritis also may be caused by Neisseria gonorrhoeae.

Clinical Features. Clinically the involved joint appears red and swollen and is extremely tender; an overlying puncture wound may be visible. The joint is held in a position that maximizes its volume, and passive motion of the joint, however slight, is painful. In contrast with flexor tenosynovitis, tenderness is localized to the involved joint.113 Pain also may be elicited by axial compression of the joint. The diagnosis is made by arthrocentesis.

Management. Treatment includes parenteral antibiotics with a semisynthetic antistaphylococcal penicillin and emergent débridement of infected bone and sequestra.114 Wounds should be splinted in extension, and referral to a hand surgeon is advised because multiple injections or surgical release may be required.

Ganglion

A ganglion is the most common soft tissue tumor of the hand and consists of a synovial cyst from either a joint or the synovial lining of a tendon that has herniated. Ganglia contain a jelly-like fluid that is secreted by the synovial tissue. They are common in the wrist and the flexor tendon sheaths of the fingers and usually have an insidious onset. Patients rarely recall a specific inciting traumatic event.114 Patients commonly complain of a dull ache or mild pain over the ganglion. Reassurance is important, and the patient should be informed of the benign nature of the lesion. A large or troublesome ganglion can be aspirated. Because of the high rate of recurrence, definitive treatment is operative excision, which is done on an elective basis.115

Foreign Bodies in the Hand

Penetrating trauma to the hand may result in a foreign body becoming lodged in the soft tissues. The presence of a foreign body should be considered in any wound regardless of its size. A detailed and accurate history of the injury should be obtained because the mechanism often gives clues to the possibility of a foreign body. The most common foreign bodies are pieces of wood, glass, or metal. Useful signs of occult foreign bodies include sharp pain with deep palpation over a puncture wound, pain associated with a mass, and failure of a wound to heal or persistence of pain with movement.116

Initial examination of hand wounds should include local exploration using sterile technique in a bloodless field. After exploration and removal of easily accessible foreign bodies, radiographs should be taken, using soft tissue technique with multiple views. Radiographs are the best method for detecting radiopaque foreign bodies and detect metals, most glass, many plashtics, gravel, and sand.117 Wooden foreign bodies are difficult to visualize radiographically.118 Whether an object shows up on plain radiographs depends on its composition, configuration, size, and orientation. When a foreign body is clinically suspected and the initial radiographic appearance is normal, other imaging methods should be considered. The identification of nonmetallic objects such as splinters may be improved by the use of modalities including computed tomography, magnetic resonance imaging, and ultrasound studies.118,119

Management. Removal of embedded foreign bodies can be difficult and time-consuming, and potential damage to tissues caused by the procedure must be weighed against the risk posed by the specific foreign body. Generally, if a foreign body contaminating a wound is clearly visible and likely to be easily extractable during local exploration, it should be removed in the ED. In some cases, the entrance wound may need to be enlarged with a small skin incision. In general, foreign bodies should be removed only under direct vision. When the object is buried within the intricate anatomy of the hand, this procedure should be deferred to a hand specialist.

Decisions regarding the necessity and timeliness of removal of a foreign body are based on the size and the reactivity of the foreign body, proximity to vital structures, degree of wound contamination, and presence or absence of symptoms.116 Foreign bodies that cause continued pain, interfere with hand function because of their size or their position, or cause local or systemic toxicity (e.g., paints or mercury) should be removed. With foreign bodies associated with fractures, prompt surgical débridement is necessary to prevent osteomyelitis.115 Wounds that are grossly contaminated with soil or organic material
require immediate irrigation, débridement, and removal of the foreign body. Foreign bodies near tendons, nerves, and vessels and foreign bodies causing ischemia or hemorrhage require cautious removal under optimal conditions.

Patients who do not require immediate removal of the foreign body may be referred to a hand surgeon for delayed surgical exploration. If the hand specialist plans to remove the object within 3 to 4 days after injury, and if bacterial contamination is minimal, the wound may be closed primarily. Initial treatment also should include tetanus prophylaxis and an appropriate wound dressing. The patient should be informed about the presence of the foreign body and the reason for delayed removal. If no removal is planned, the physician should explain to the patient that the dangers of removal outweigh the benefits.

Complications. Foreign bodies can damage soft tissues, provoke excessive inflammation with granuloma formation, predispose the patient to infection, and cause systemic toxicity. Iatrogenic damage to tissue can result from blind probing or excessively aggressive searches for foreign bodies; such maneuvers should be avoided, particularly in the hand.

**KEY CONCEPTS**

- Injuries and infections of the hand are among the most commonly encountered problems in the ED.
- An accurate history and carefully performed physical examination of the hand have a central role in evaluation and treatment. Hand radiographs should be obtained if suggestive signs are present. High-technology diagnostic modalities are rarely indicated.
- The best functional outcomes of hand injuries usually are achieved by accurate initial evaluation and treatment.
- A key factor in the evaluation of hand injuries is determining which entities require specialty referral or urgent consultation.
- Management of the injured hand should focus on restoring function and minimizing long-term disability.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
The wrist is anatomically and biomechanically complex. This complexity allows for its diverse functional capabilities, but also puts it at risk for injury. Bony and ligamentous injuries are common, and a detailed knowledge of relevant anatomy and appropriate clinical evaluation and an understanding of mechanism of injury are essential for proper diagnosis and treatment. Although certain wrist injuries may provide a diagnostic challenge, most are evident on routine radiographic views and can be diagnosed and treated by an emergency physician.

Anatomy

By definition, the wrist includes the distal radioulnar joint (DRUJ), the radiocarpal joint, and the midcarpal joints. With these complex articulations, the wrist is capable of flexion, extension, and radial and ulnar deviation. Pronation and supination of the hand occur at the proximal radioulnar joint and the DRUJ.

The bones of the wrist joint include the distal articular surfaces of the radius and ulna and the bones of the carpus (Fig. 48-1). The distal radius articulates directly with the proximal carpal row, and the articular surface of the ulna is separated from direct contact with the carpus by the triangular fibrocartilage. The carpal bones are divided into two rows: a proximal row consisting of the scaphoid, lunate, triquetrum, and pisiform and a distal row consisting of the trapezium, trapezoid, capitate, and hamate.

The stabilizing ligaments of the wrist joint are divided into two major groups: the extrinsic ligaments and the intrinsic ligaments. The extrinsic ligaments link the carpal bones to the distal radius and ulna and the metacarpals, and the intrinsic ligaments interconnect the individual carpal bones. The extrinsic ligaments are divided further into a volar and a dorsal group. The volar extrinsic ligaments are divided into two V-shaped ligamentous bands called the proximal and distal arcades, which generally are thicker and stronger than the dorsal extrinsic ligaments and are the most important in providing ligamentous stability to the wrist. Between these volar arcades is an area relatively devoid of ligamentous support called the space of Poirier. This space enlarges when the wrist is dorsiflexed, and an injury to the joint capsule in this region can result in significant carpal instability (Fig. 48-2). The intrinsic ligaments interconnect adjacent carpal bones within each carpal row. The most important of these ligaments for maintaining carpal stability are the scapholunate and lunotriquetral ligaments.

Most structures that cross the wrist joint are contained within individual compartments formed by the deep fascia of the wrist. On the dorsal surface of the wrist, the extensor tendons are divided by the extensor retinaculum into six compartments, each having a separate synovial sheath that extends proximal and distal to the retinaculum. On the volar surface of the wrist, the flexors of the digits and the median nerve are contained within the carpal tunnel, which is formed by the flexor retinaculum and its attachments to the carpal bones. Radial to the carpal tunnel, the flexor carpi radialis tendon crosses the wrist joint in its own compartment.

The vascular supply to the wrist is provided by the radial and ulnar arteries, which join in a series of dorsal and palmar arches to supply the bones of the carpus. The intrinsic blood supply to most carpal bones enters the distal portion of the bone, leaving the proximal portion at risk for devascularization and avascular necrosis when fractured. This is particularly true for the scaphoid, capitate, and lunate because they each receive their blood supply from a single vessel (Fig. 48-3).

The innervation of the wrist and hand is by the radial, median, and ulnar nerves. The radial nerve and the dorsal sensory branch of the ulnar nerve cross the dorsum of the wrist near the radial and ulnar styloids. The median nerve crosses the volar radial aspect of the wrist within the carpal tunnel, just lateral to the palmaris longus tendon, and the ulnar nerve is within Guyon’s canal between the pisiform and the hook of the hamate (see Fig. 48-3).

Clinical Features

The clinical examination of the patient with a wrist injury begins with a complete history, including the mechanism of injury and the site of maximal pain or tenderness. Most wrist injuries are caused by a fall on the outstretched hand. The physical examination begins with inspection of the wrist, using the opposite noninjured wrist as the “normal” reference, and includes an assessment of the presence of swelling, discoloration or obvious deformity, and the ability of the patient to move the joint through a normal range of motion.

On palpation, several bony prominences in the wrist serve as useful landmarks, and the locations of these are best described in relation to the major reference points in the
wrist—the radial and ulnar styloids. Listers tubercle can be palpated on the dorsum of the wrist just ulnar to the radial styloid. This is an important landmark because just distal to the tubercle lies the scapholunate joint, an important site of ligamentous injury in the wrist. Just distal to the radial styloid is the anatomic snuffbox, bordered radially by the abductor pollicis longus and extensor pollicis brevis tendons and ulnarly by the extensor pollicis longus tendon. The body of the scaphoid is palpable within the snuffbox and is more prominent with wrist in ulnar deviation.1 The triquetrum is palpable within the snuffbox and is more prominent with radial deviation of the wrist, the pisiform is palpable at the base of the hypothenar muscles, just distal to the distal wrist crease. In addition, approximately 1 cm distal and radial to this point, one can palpate the prominence formed by the hook of the hamate.

The clinical examination also includes an assessment of the neurovascular status. Radial and ulnar pulses are easily palpable on the volar surface of the wrist, and the presence of pulses should be documented in all injuries to the wrist.

## DIAGNOSTIC STRATEGIES: RADIOLOGY

Plain radiographs remain the cornerstone of diagnosis of fractures and dislocations of the wrist. Routine radiographic views include the posteroanterior, lateral, and oblique projections, each obtained with the wrist in neutral position. Accurate interpretation of these views requires knowledge of the normal appearance and anatomic relationships of the distal radius, ulna, and carpal bones.

On the posteroanterior view of the wrist, the radial styloid process extends beyond the end of the articular surface of the ulna by a normal distance of 9 to 12 mm. This normal difference in length is called the radial length measurement. The ulnar slant of the articular surface of the radius, referred to as radial inclination, is visible on the posteroanterior view and normally measures 15 to 25 degrees. Both of these measurements are important in assessing the degree of radial shortening seen in association with some fractures of the distal radius (Fig. 48-4).2 The normal appearance of the carpus on the posteroanterior view shows an approximately equal distance (usually 1 to 2 mm) between each of the carpal bones, and opposing articular surfaces are parallel to one another (an arrangement known as parallelism). On radiographs, three smooth curves normally can be drawn along the carpal articular surfaces (Fig. 48-5). Disruption of these curves or widening of the carpal spaces is an indication of carpal ligament disruption and carpal instability.3

On the lateral view of the wrist, the normal volar tilt of the distal radial articular surface is visible and normally measures between 10 and 25 degrees (Fig. 48-6). The normal alignment of the distal radius with the lunate and capitale is also seen on the lateral view, which will show two concentric cups, the cup of the distal radius containing the lunate and the cup of the distal lunate containing the capitale. Ideally the long axis of the radius, lunate, capitale, and third metacarpal should appear as a straight line on the lateral view, although the “normal” alignment usually is within 10 degrees of this ideal line (Fig. 48-7). The carpal alignment on the lateral view is defined further by the scapholunate angle, which normally measures 30 to 60 degrees, and the capitolunate angle, which in normally is 0 to 30 degrees (Fig. 48-8). Abnormalities in these angles are seen in patients with carpal ligament injuries and carpal instability.

The soft tissues of the wrist also offer valuable clues to the presence of underlying bony injuries. On the lateral view of the wrist, the pronator quadratus line is visible as a linear bony collection in the volar soft tissues just anterior to the distal radius and ulna (Fig. 48-9). Fractures of the distal radius or ulna result in volar displacement or complete obliteration of this line.

Additional radiographic views of the wrist include posteroanterior views in ulnar and radial deviation, lateral views in maximal flexion and extension, and the clenched-fist anteroposterior view. These views are useful to delineate further abnormal motion of the carpus resulting from carpal ligament injuries. Specific scaphoid views, obtained with the wrist
pronated and in ulnar deviation, allow for better visualization of the scaphoid along its long axis. The carpal tunnel view is performed with the wrist hyperextended and provides an axial view of the bony margins of the carpal tunnel. This view and the reverse (supinated) oblique view help identify fractures involving the hamate, especially the hook of the hamate, and the pisiform (Table 48-1).

### CARPAL INJURIES

#### Scaphoid Fractures

The scaphoid is the most commonly fractured of the carpal bones and accounts for more than 62 to 87% of all carpal fractures. This fracture typically is seen in young adults 15 to 30 years of age and occurs after a fall on the outstretched hand.
Figure 48-3. Vascular supply to the wrist. Note the relationship of the wrist ligaments to the neurovascular supply to the wrist. (Redrawn from Netter FH: Atlas of Human Anatomy, 3rd ed. Teterboro, NJ, Icon, 2003.)

Figure 48-5. Wrist arcs. On a posteroanterior radiographic view of a normal carpus, three arcuate lines (labeled 1 to 3) can be drawn along the carpal articular surfaces. (From Weissman BN, Sledge CB: Orthopedic Radiology. Philadelphia, Saunders, 1986.)
Figure 48-6. Normal radiographic appearance of the wrist on a lateral view. The distal radius has a normal volar tilt of 10 to 25 degrees. (From Greenspan A: Orthopedic Radiology: A Practical Approach, 2nd ed. New York, Gower Medical Publishing, 1992.)

Figure 48-7. Normal relationship of carpal bones on a lateral radiographic view. Concavity of radius and lunate and convexity of capitae form three C-shaped areas (stippled) along a straight line that runs through the central axis of these bones.

Figure 48-8. A, The normal scapholunate angle is formed by the intersection of the longitudinal axes of the scaphoid and lunate and normally measures 30 to 60 degrees. B, The normal capitolunate angle is formed by the intersection of the capitae and lunate central long axes and normally measures 0 to 30 degrees. (From Greenspan A: Orthopedic Radiology: A Practical Approach, 2nd ed. New York, Gower Medical Publishing, 1992.)

Figure 48-9. The pronator quadratus is a narrow fat stripe (arrow) located 1 cm from the volar surface of the radius on the normal lateral wrist view. (From Propp DA, Chin H: Forearm and wrist radiology—Part I. J Emerg Med 7:393, 1989.)
Fractures of the scaphoid are classified by the anatomic location of the fracture line and may be divided into three groups: fractures of the tuberosity and distal pole, fractures of the wrist, and fractures of the proximal pole. Fractures through the wrist of the scaphoid are the most common of these three patterns and account for approximately 70 to 80% of all scaphoid fractures.\(^7\)

Clinically, patients complain of dorsal radial wrist pain just distal to the radial styloid, with limited range of motion of the wrist and thumb. Classically, physical examination reveals tenderness on palpation of the scaphoid and swelling within the anatomic snuffbox. Pain also may be elicited with palpation of the scaphoid tubercle, with axial compression of the thumb metacarpal, with resisted supination, and with limited thumb range of motion and pain at the end of arc of motion, especially with flexion and radial deviation.\(^9,10\) Overall, clinical examination has excellent sensitivity for identification of fracture, but low specificity (74 to 80%).\(^9,10\)

Radiographic diagnosis of scaphoid fractures often is difficult, and special scaphoid views should be requested when a fracture is suspected on the basis of the clinical findings. A visible fracture lucency may be occult, and a more subtle change such as obliteration or displacement of the scaphoid fat pad may be the only clue to the presence of a fracture, although these signs are not reliably present.\(^11\) Plain radiographs taken soon after injury fail to detect 14% of scaphoid fractures.\(^12\) For this reason, and because of the associated risk of nonunion when diagnosis and immobilization are delayed, patients clinically suspected of having a scaphoid fracture were often treated with cast immobilization. Recent evidence, however, has called into question the practice of immobilizing the wrist in all patients with suspected scaphoid injuries and has suggested that the use of more advanced imaging modalities is both accurate and cost-effective and that such studies should be performed earlier rather than later. Cost of time off work and serial casting and office visits easily exceed the cost of a magnetic resonance imaging (MRI) study or computed tomography (CT) scan for definitive diagnosis.\(^13,14\)

Historically, bone scans were used 72 to 96 hours after injury to detect scaphoid fracture.\(^15,16\) Currently, MRI is used to detect these radiographically occult fractures, with sensitivity rates of 100%. A strong correlation has been shown between bone scan and MRI of the scaphoid.\(^16,17\)

Treatment of uncomplicated, undisplaced scaphoid fractures involves immobilization in a short arm thumb spica cast (Fig. 48-10), although some specialists prefer to use a long arm cast for the first 2 weeks of immobilization, replacing this with a short arm cast for the remainder of the immobilization period. The duration of immobilization varies relative to the location of the fracture but averages 12 weeks, with the more proximal fractures requiring longer immobilization to ensure adequate healing. This variability in healing time is related directly to the pattern of blood supply to the scaphoid, which flows from the distal to the proximal portion of the bone through the scaphoid tuberosity. This pattern of blood flow also accounts for the higher incidence of avascular necrosis (AVN) and fracture nonunion in the more proximal fractures. Overall, AVN is seen in approximately 13 to 40% and nonunion in 5 to 12% of scaphoid fractures, with the risk of complications being greatest in fractures of the proximal pole.\(^18-20\) Because of the increased risk of AVN or nonunion, any scaphoid fracture that is displaced more than 1 mm or is associated with an increase in the normal scapholunate or capitolunate angles requires prompt orthopedic referral for consideration of operative treatment.

### Lunate Fractures

Fractures of the lunate are relatively uncommon, representing fewer than 1.4% of all carpal fractures.\(^21\) This injury occurs more commonly in persons with a congenitally short ulna, owing to compromise of the normal triangular fibrocartilage support. The usual mechanism of injury involves a fall on the outstretched hand, causing extreme dorsiflexion, with transmittal of the resultant force from the capitate to the lunate. Patients have pain over the dorsum of the wrist, which is exacerbated by axial loading of the long finger metacarpal. On examination, tenderness may be elicited by palpation over the dorsum of the wrist in the depression felt just distal to Lister’s tubercle.

Fractures of the lunate may be difficult to see on plain radiographs because of overlap of the distal radius, ulna, and other carpal bones. For this reason, and because of the risk of avascular necrosis in missed injuries, suspected lunate fractures should be immobilized in a short arm cast until a fracture can be confirmed or excluded by CT or MRI.

Lunate fractures are treated with immobilization in a short arm cast, with orthopedic follow-up evaluation in 1 to 2 weeks. Complications include progression to carpal instability, nonunion, and AVN. Posttraumatic AVN is a sequela in 20% of fractures and is called Kienbock’s disease. In well-established

cases of Kienbock’s disease, the lunate appears sclerotic and fragmented on radiographic examination, and ultimately the bone collapses with resultant proximal migration of the capitare. These changes cause secondary osteoarthritis of the radiocarpal joint and chronic wrist pain. Treatment involves operative intervention, with correction of the articular abnormalities either by lengthening the ulna or by shortening the radius. In more advanced cases, excision and prosthetic replacement of the lunate or arthrodesis may be necessary.22

**Triquetral Fractures**

Fracture of the triquetrum, the second most common fracture of the carpals, usually results either from a direct blow to the bone, causing a fracture of the body, or from a fall on the outstretched hand. In the latter scenario, the mechanism of fracture is believed to be impact of the ulnar styloid or proximal hamate against the triquetrum, which results in a dorsal chip fracture.23 Patients have localized tenderness over the dorsum of the wrist just distal to the ulnar styloid. On physical examination, swelling may be noted in this area, and wrist motion is limited because of pain. The fracture is best seen on the standard lateral view of the wrist as a small dorsal chip fragment, although a more oblique pronated lateral view may be necessary (Fig. 48-11). Treatment with immobilization in a short arm cast or splint usually results in an uncomplicated course, with prompt fracture healing over 4 to 6 weeks.

**Pisiform Fractures**

The pisiform is a unique carpal bone because it is a sesamoid bone that lies within the flexor carpi ulnaris tendon and articulates on its dorsal surface with the triquetrum. Fractures of the pisiform usually occur from a fall on the outstretched hand but also may be seen with direct blows to the hypothenar eminence. On clinical examination, there is tenderness over the ulnar aspect of the volar wrist crease, which may be exacerbated with wrist flexion and ulnar deviation.24 Fractures of the pisiform can impinge on Guyon’s canal, resulting in ulnar nerve injury. Paresthesias in the distribution of the ulnar nerve and hand clumsiness from intrinsic muscle dysfunction can occur. Pisiform fractures are poorly seen on routine wrist radiographs, so special views must be requested. A reverse (supinated) oblique view and the carpal tunnel view allow for better visualization of these fractures.4

Fractures of the pisiform generally carry an excellent prognosis and are treated with immobilization in a short arm cast or splint for 3 to 4 weeks. In injuries with evidence of nerve compromise, orthopedic consultation for possible urgent surgical decompression is indicated to restore nerve function. Fractures that are complicated by nonunion may require excision of the pisiform to prevent chronic pain.

**Hamate Fractures**

Hamate fractures are rare and account for approximately 2% of all carpal bone fractures. The hook or hamulus is the most common site of fracture, although fractures through the articular surfaces and body also are seen. Fracture of the hook usually occurs from a fall on the outstretched hand or from a direct blow to the palm of the hand. Commonly, the use of hammers and vibration from equipment also can cause fractures. Patients present with pain over the hypothenar eminence with associated decreased grip strength. Pain may be localized on palpation of the hamate, 1 cm distal and radial to the pisiform. Fractures of the hamate body and articular surface usually are seen on posteroanterior views of the wrist, but fractures of the hook are seen best on the reverse oblique and carpal tunnel views.4 When findings on these views are inconclusive, a CT scan may allow confirmation of fracture.5,25 Plain radiographs can detect 71% of hamate fractures, whereas CT scan is 100% sensitive.5

Initial treatment is by immobilization in a short arm cast with orthopedic follow-up evaluation in 1 to 2 weeks. Fractures of the hook of the hamate often are complicated by associated ulnar nerve injury or progression to nonunion. In both instances, operative intervention with excision of the hook at the fracture site is necessary.5

**Trapezium Fractures**

Fractures of the trapezium are uncommon and represent only 1 to 5% of all carpal injuries. There are two main types of fractures: fractures involving the body and fractures involving the trapezial ridge. A direct blow to the adducted thumb causes fracture through the body of the trapezium, with transmittal of the force by the base of the thumb metacarpal. Avulsion fractures of the trapezial ridge occur with forceful radial deviation or rotation of the wrist. On examination, patients complain of pain with movement of the thumb and on direct palpation of the trapezium just distal to the scaphoid in the anatomic snuffbox. Fractures are seen best on slightly pronated oblique views of the wrist, although a true anteroposterior view of the trapezium (Roberts’ view) or CT scan may be necessary.26 These injuries are treated with immobilization in a thumb spica cast for 6 weeks, unless the fracture is displaced or involves the carpometacarpal joint, in which case referral for open reduction and fixation is indicated.
Part II

Trauma

Section Three

• Orthopedic Lesions

Capitate Fractures

The capitate lies in a central position in the distal carpal row, and because of this protected location, it is rarely fractured. When fracture does occur, the mechanism generally is a direct blow to the dorsum of the wrist. Fracture also may be seen in association with a perilunate dislocation after a fall on the outstretched dorsiflexed hand. Clinical examination reveals dorsal wrist pain and swelling, with localized tenderness on palpation of the capitate. Fractures usually are visible on the standard posteroanterior view of the wrist, although the lateral view may be helpful in determining the presence of rotation or displacement of the fracture fragment.

Undisplaced isolated fractures of the capitate may be managed with immobilization in a short arm cast for 6 weeks. Any fracture with displacement or associated carpal dislocation requires prompt orthopedic referral for open reduction and fixation. Complications of nonunion and avascular necrosis of the proximal fragment are rare, but do occur, because the capitate receives its blood supply through its distal half.24

Trapezoid Fractures

The trapezoid rarely is fractured; such fractures account for less than 1.3% of all carpal bone fractures.3 Trapezoid fractures most commonly are seen in association with other carpal fractures. The typical mechanism of injury is a direct blow down the long axis of the index metacarpal, which may result in isolated fracture to the trapezoid or may cause a dorsal fracture-dislocation. On clinical examination, pain and tenderness are localized over the dorsum of the wrist at the base of the second metacarpal. The fracture may be visible on routine posteroanterior views of the wrist; however, oblique views or CT may be necessary to visualize this injury. Undisplaced fractures are treated with immobilization in a short arm cast for 6 weeks, and fracture-dislocations warrant prompt orthopedic referral for reduction and fixation.24

Carpal Instability

Mayfield and associates27 described a progressive pattern of carpal ligamentous injury caused by wrist hyperextension, ulnar deviation, and intercarpal supination. Their studies of the pathomechanics of these injuries led to the classification of carpal instability into four distinct stages. Each stage represents a sequential intercarpal injury beginning with scapholunate joint disruption and proceeding around the lunate, creating progressive carpal instability (Fig. 48-12). Each stage also may be associated with specific bony fractures, which if present should alert the physician to the possibility of an occult perilunate ligamentous injury. These associated fractures include fractures of the radial styloid, scaphoid, capitate, and triquetrum.

A stage I injury, or scapholunate dissociation, results in a characteristic widening of the scapholunate joint on the posteroanterior view, which has been called the “Terry Thomas sign,” after the British comedian with a gap between his front teeth.28 If associated with rotary subluxation of the scaphoid, the scaphoid is seen end on with the cortex of the distal pole appearing as a ring shadow over the scaphoid; this is called the signet ring sign (Fig. 48-13). The radiographic appearance may be normal on routine views, so when a scapholunate ligament injury is suspected clinically, additional stress views should be obtained. Views taken with a clenched fist and with ulnar deviation (the clenched-fist anteroposterior view) accentuate widening of the scapholunate joint.

A stage II injury, or perilunate dislocation, is seen best on the lateral view of the wrist. Although the lunate remains in position relative to the distal radius, the capitate is dorsally dislocated. The posteroanterior view shows overlap of the distal and proximal carpal rows and also may show an associated scaphoid fracture or subluxation29 (Fig. 48-14).

A stage III injury appears identical to a stage II injury but includes a dislocation of the triquetrum that is seen best on the posteroanterior view, with overlap of the triquetrum on the lunate or hamate. This injury may be associated with a volar triquetral fracture.
A stage IV injury, or lunate dislocation, results in a characteristic triangular appearance of the lunate on the posteroanterior view that is due to the rotation of the lunate in a volar direction. This triangular appearance is known as the “piece of pie sign.” This rotation also is visible on the lateral view of the wrist, in which the lunate looks like a cup tipped forward and spilling its contents into the palm. This latter appearance is called the “spilled teacup sign.” On the lateral view, the capitae are seen to lie posterior to the lunate and often has migrated proximally to contact the distal radius (Fig. 48-15).

Patients with these carpal dislocation injuries typically have a history of a fall on the outstretched hand. They complain of pain and swelling over the dorsum of the wrist, with limited range of motion. On physical examination, tenderness to palpation is noted over the dorsum of the wrist, particularly in the region of the scapholunate ligament. With perilunate and lunate dislocations, visible deformity of the wrist also is apparent, and two-point sensation in the median nerve distribution often is diminished. A provocative maneuver such as Watson’s scaphoid shift test often will increase pain and produce a clunk or snap.30 Complications of carpal dislocation injuries include median nerve injury and chronic carpal instability with resultant degenerative arthritis.

Bone scintigraphy is a nonspecific test for scapholunate instability. It may be somewhat useful when findings are negative; however, positive findings simply localize the site of injury. MRI has been shown to have relatively low sensitivity (63%) and specificity (86%) for the diagnosis of scapholunate injury.31,32 Arthroscopy has become the “gold standard” modality for identifying and grading scapholunate injuries. It allows superior detection of internal derangement of wrist ligaments and a more accurate visualization of the articular surfaces.33

Carpal dislocation injuries require orthopedic consultation in the emergency department for reduction and stabilization. Either arthroscopically guided reduction and pinning or open reduction with ligament repair is now recommended for the optimal management of these acute injuries.

**Intercalated Segment Instability**

Not all patterns of carpal instability follow the pattern described by Mayfield and associates.29 Two other common types of carpal instability—dorsal intercalated segment instability (DISI) and volar intercalated segment instability (VISI)—are better understood as a pattern of midcarpal joint collapse (Fig. 48-16). These patterns of carpal instability are recognized radiographically by specific deformities on the lateral view of the wrist (Fig. 48-17).

With the DISI pattern of instability, there is dorsiflexion of the lunate relative to the capitae, which results in an increase in the scapholunate and capitolunate angles. With the VISI pattern of instability, there is volar flexion of the lunate relative to the capitae, with a decrease in the scapholunate angle and an increase in the capitolunate angle. These angles are best visualized on the lateral view radiograph, on which the articular surface of the lunate appears to be tilting dorsally (in DISI) or volarly (in VISI). DISI is the most common pattern of carpal instability and may occur after scapholunate dissociation or with scaphoid fractures with or without associated perilunate dislocation. VISI occurs after lunotriquetral or triquetrolunate joint disruption. Either pattern may be seen in association with radiocarpal joint malalignment, as is seen in lunate collapse with Kienbock’s disease, rheumatoid arthritis, or congenital carpal ligamentous laxity.34,35
Clinically, patients have chronic pain, weakness, and limited range of motion of the wrist and may complain of the wrist clicking with ulnar deviation. On physical examination, point tenderness can be elicited over the area of primary injury, usually the scapholunate or lunotriquetral joints. Gross deformity of the wrist, resulting from subluxation, also may be apparent on comparison with the unaffected “normal” wrist. Patients should be referred to an orthopedic surgeon for definitive treatment of these injuries. Operative treatment involves reduction and stabilization, with ligamentous reconstruction or repair.

**DISTAL RADIUS AND ULNA INJURIES**

**Colles’ Fracture**

Colles’ fracture, first described in 1814, is the most common wrist fracture seen in adults. It is a transverse fracture of the distal radial metaphysis, which is dorsally displaced and angulated. The fracture usually is located within 2 cm of the radial articular surface and may be associated with intra-articular extension into the radiocarpal or radioulnar joints. There is commonly an associated fracture of the ulnar styloid.

Clinically, patients have a history of a fall on the outstretched hand and complain of immediate pain and swelling over the dorsum of the wrist. On examination, there is an obvious “dinner fork” deformity of the wrist caused by the dorsal displacement and angulation of the fracture. A neurovascular examination should be performed to exclude an associated median nerve injury or vascular compromise caused by this deformity or by fracture fragments.

The posteroanterior and lateral views of the wrist show the fracture through the radial metaphysis. The posteroanterior view may show extension of the fracture into the radioulnar or radiocarpal joints and shows the amount of radial shortening present. The degree of dorsal displacement and angulation is best seen on the lateral view, with loss of the normal volar tilt of the distal radial articular surface (Fig. 48-18).

Colles’ fracture requires early anatomic reduction with full restoration of radial length and correction of the dorsal angulation either to a neutral position or ideally to the normal volar tilt position. Closed reduction, using local or regional anesthesia, with cast immobilization is successful in most cases (Fig. 48-19). An effective method of anesthesia is placing a 22-gauge needle in the dorsum of the distal radius, withdrawing until a hematoma is encountered, then instilling 5 to 10 mL of 2% lidocaine (Xylocaine) (Fig. 48-20). Use of finger traps also is an effective means of obtaining the reduction to allow positioning for casting (Fig. 48-21). The more comminuted and
displaced the fracture, the more likely it is that operative reduction will be necessary. Complicated fractures with significant displacement (more than 20 degrees of dorsal angulation), marked dorsal comminution, or intra-articular extension merit close follow-up by an orthopedic specialist, because loss of reduction is frequent with these injuries, mandating early operative reduction with internal or external fixation. Immediate referral to an orthopedic surgeon should be considered if initial attempts at closed reduction are unsuccessful, if there is associated neurovascular compromise, or if the fracture is open. (Table 48-2).

Complications of Colles’ fracture are seen most often in elderly patients and in patients with inadequate fracture reduction.37,38 Median nerve injury may occur acutely either from traction from the original fracture displacement or with direct injury to the nerve by fracture fragments. Injury to the median nerve also has been described after closed reduction because of traction on the nerve, direct pressure from the cast or related to position of immobilization, or swelling causing compression in the carpal tunnel. Treatment entails repositioning, decreasing the splint pressure, or occasionally carpal tunnel release. For this reason, it is important to document neurologic function before and after fracture reduction. A more common complication is malunion of the fracture, resulting in chronic wrist pain and limited range of motion. This

complication is more likely to arise in cases of fracture involving the radiocarpal joint.

**Smith’s Fracture**

Smith’s fracture is a transverse fracture of the metaphysis of the distal radius, with associated volar displacement and volar angulation. In some cases, the fracture may extend into the radiocarpal joint. Because the resultant deformity is opposite to that seen in Colles’ fracture, Smith’s fracture often is called a *reverse Colles’ fracture*. The typical mechanism of injury involves a direct blow to the dorsum of the wrist or a fall onto the dorsum of the hand resulting in extreme palmar flexion. The fracture also may be seen after a fall backward on an outstretched hand with the forearm in supination. The patient has a swollen, painful wrist, which is deformed, with fullness visible on the volar aspect. The fracture is visible on posteroanterior and lateral radiographs of the wrist, but the lateral view best shows the degree of volar displacement and angulation (Fig. 48-22).

Treatment of this fracture involves closed reduction with cast immobilization for 6 to 8 weeks; however, molding of the cast to maintain the reduction can lead to median nerve compression. Orthopedic consultation is recommended because open reduction and internal fixation may be required. Complications include median nerve injury, malunion, and posttraumatic arthritis, especially in fractures with significant displacement or intra-articular extension. As with Colles’ fracture, prognosis is most favorable in patients with successful reduction, with restoration of the normal radial length and volar tilt.39

**Barton’s Fracture**

Barton’s fracture is an oblique intra-articular fracture of the rim of the distal radius, with displacement of the carpus along with the fracture fragment. The fracture may involve the dorsal rim of the radius with dorsal carpal subluxation (classic Barton’s fracture), or it may involve the volar rim with volar carpal subluxation (volar Barton’s fracture). These fractures are rare and account for only 0.5 to 1.6% of all distal radius fractures.42

The volar–anterior margin fracture is seen more often than the dorsal–posterior margin fracture.

The mechanism of injury for these fractures is a high-velocity impact across the articular surface of the radiocarpal joint, with the wrist in either volar flexion (causing a volar rim fracture) or dorsiflexion (causing a dorsal rim fracture). Volar and dorsal rim fractures are easily visible on posteroanterior and lateral wrist radiographs; however, the lateral view best shows the degree of articular surface involvement and the amount of associated fracture displacement (Fig. 48-23).

Treatment of these fractures requires orthopedic consultation for reduction and stabilization. Closed reduction occasionally may be successful. Most authorities now advocate early operative management, however, with either closed reduction performed under fluoroscopy followed by percutaneous pinning or open reduction and internal fixation to restore accurately the articular surface of the radius and stabilize the carpus.40 Complications include posttraumatic arthritis of the radiocarpal joint and delayed carpal instability. Both complications are seen more commonly when reduction fails to achieve or maintain anatomic realignment of the radiocarpal joint surface.

**Hutchinson’s Fracture**

Hutchinson’s fracture, or chauffeur’s fracture, is an intra-articular fracture of the radial styloid. The mechanism of injury is usually a direct blow or fall resulting in trauma to the radial side of the wrist. The term chauffeur’s fracture originated in the era of hand-cranked automobiles, when this injury occurred because of direct trauma to the radial side of the wrist from the recoil of the crank. The fracture is seen best on the posteroanterior view of the wrist, as a transverse fracture of the radial metaphysis with extension through the radial styloid into the radiocarpal joint (Fig. 48-24).

Nondisplaced fractures may be immobilized in a short arm cast for 4 to 6 weeks; however, displaced fractures require open or closed reduction and fixation. Because the radial styloid is the primary site of attachment for many of the ligaments of the wrist, accurate fracture reduction and union are crucial.41 Complications of radial styloid fracture include associated scapholunate ligament disruption and posttraumatic arthritis, both of which are more likely when there is fracture displacement.

**Radioulnar Joint Disruption**

Dislocation of the DRUJ may be seen in association with distal radial fractures and Galeazzi’s fractures. It also may be seen as an isolated injury without fracture. Diagnosis often is difficult because plain radiographs commonly are reported as normal in appearance, so certain characteristic findings on careful clinical examination may constitute the only clue to the presence of this injury.

The typical mechanism of injury is a fall on the outstretched hand with either hyperpronation, resulting in dorsal dislocation, or hypersupination, causing volar dislocation of the ulna. Another mechanism known to cause DRUJ dislocation is that
obtained when the hand is caught in rotating machinery, resulting in the same forcible hyperpronation or supination. This forcible rotation of the wrist causes disruption of the triangular fibrocartilage complex, the major stabilizer of the DRUJ, and may result in an associated avulsion fracture of the ulnar styloid.

Patients with this injury have a history of sudden onset of pain with a "snapping" sensation in the wrist, swelling, and limited range of motion. On examination, tenderness is present over the ulnar aspect of the wrist, with palpable crepitus on supination and pronation. With a dorsal dislocation of the ulna, the ulnar styloid appears more prominent than on the unaffected side, and significant pain and limitation of movement are noted on supination of the wrist. With a volar dislocation of the ulna, there is loss of the normal ulnar styloid prominence, with pain and limitation of movement on pronation. These characteristic clinical findings should alert the physician to the possibility of DRUJ disruption and prompt the appropriate investigations to confirm the presence or absence of this injury.

Plain radiographs of the wrist may show the presence of DRUJ dislocation, but pain and inability of the patient to rotate the wrist fully may cause a false-negative result because a true lateral view cannot be obtained. It also is important to assess for radial head fractures because these fractures commonly are associated with DRUJ disruption. If there is significant clinical suspicion of injury and the radiographic appearance is normal, a CT scan of the DRUJ is recommended.

Treatment of these acute injuries requires orthopedic consultation for reduction and stabilization. Closed reduction with the forearm in supination followed by application of a long arm cast often is successful. Alternatively, open reduction frequently is necessary with volar dislocations because the ulnar head often is locked on the volar distal radius. Operative reduction also is necessary in dorsal dislocations to repair the associated injury to the triangular fibrocartilage complex. Immobilization in a long arm cast usually is maintained for 6 weeks.

**Pediatric Fractures of the Distal Radius**

Fractures of the distal radius in children may be divided into two types: fractures involving the distal radial metaphysis and fractures involving the growth plate. They usually occur as a result of a fall on an outstretched hand with the wrist forcibly dorsiflexed. Fractures of the radial metaphysis are of three types: torus fractures, greenstick fractures, and complete fractures.

The torus fracture is the most common of these fractures and results in a buckling of the radial cortex, which, because of the strong periosteum, occurs without significant displacement (Fig. 48-25). These fractures are treated with immobilization in a short arm cast with orthopedic follow-up evaluation. Healing usually occurs over 2 to 3 weeks, and complications are rarely seen.

Greenstick fractures also are incomplete metaphyseal fractures, with disruption of the cortex on one side and angulation or bowing on the opposite side. By definition, these fractures are displaced and require reduction achieved with use of regional or general anesthesia if angulated more than 10 degrees. Angulations of less than 10 degrees usually remodel.
Short arm well-molded cast immobilization is recommended, with close orthopedic follow-up to ensure maintenance of reduction.

Complete fractures of the radial metaphysis involve complete disruption of both cortices of bone and usually result in significant displacement and angulation. These fractures also may be associated with a fracture of the distal ulna. Closed reduction by an orthopedic surgeon with use of regional or general anesthesia may be successful, but if alignment is unsatisfactory or if the fracture is unstable, open reduction with internal fixation may be necessary.45

In 1963, Salter and Harris classified growth plate injuries in children (Table 48-3). Growth plate or physeal fractures of the distal radius are usually Salter-Harris type I or type II. Although these injuries result in disruption of the growth plate, they rarely result in growth disturbance.46 Type I injuries cause pain and palpable tenderness over the distal radial physis, with the only radiographic abnormality being volar displacement of the pronator quadratus fat pad. These injuries may be treated with a short arm cast or splint immobilization for 3 to 4 weeks; orthopedic follow-up evaluation within 1 week of the injury is advised. Type II injuries involve a fracture through the radial metaphysis and the physis and are visible on routine wrist radiographs as a triangular metaphyseal fragment on the dorsal surface of the radius (Fig. 48-26). These fractures may be complicated by displacement of the radial epiphysis or by an associated fracture of the distal ulna. If displacement is present, these injuries require orthopedic referral for closed reduction with the patient under general anesthesia and immobilization in a short arm cast for 6 weeks. Operative fixation may be necessary if adequate alignment cannot be achieved or maintained with closed reduction and casting.

#### SOFT TISSUE INJURIES OF THE WRIST

### Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is a neuropathy of the median nerve at the wrist that occurs as a result of compression of the median nerve within the carpal tunnel. CTS is one of the most common nerve entrapment syndromes, with a lifetime incidence of 5.8% in women and 0.6% in men.47 The transverse carpal ligament and the volar surfaces of the carpal bones form the carpal tunnel. It is a rigid compartment that contains nine flexor tendons (the flexor pollicis longus tendon, four flexor digitorum superficialis tendons, and four flexor digitorum profundus tendons) and the median nerve. Any process, local or systemic, that results in an increase in pressure within this compartment may produce carpal tunnel syndrome.

The most common causes of carpal tunnel syndrome are distal radius fractures and repetitive strain. Carpal tunnel syndrome also can be associated with numerous systemic conditions such as rheumatoid arthritis, hypothyroidism, diabetes mellitus, renal failure, congestive heart failure, acromegaly, and collagen vascular diseases. Each of these systemic diseases is thought to produce an increase in pressure within the carpal tunnel from thickening of the flexor synovia or transverse carpal ligament. Hormonal changes associated with pregnancy and menopause also are known to cause carpal tunnel syndrome, probably from retention of fluid in the soft tissues about the wrist.48

The classic symptoms include a gradual onset of numbness, paresthesia, and pain in the thumb, index finger, and long finger. These symptoms often are bilateral and are worse during the night and after strenuous activities. Typically,
patients report numbness and paresthesias on awakening that lessen when the hands are shaken or held in a dependent position.

Examination of the neck and chest is important to detect cervical radiculopathy or thoracic outlet syndrome, which can mimic carpal tunnel syndrome. The most sensitive provocative test is the wrist flexion test, or Phalen’s test (sensitivity of 76% and specificity of 80%)\textsuperscript{49} (Fig. 48-27). This test is performed by asking the patient to flex the wrists fully for 60 seconds while holding the forearms in a vertical position. The test result is positive if paresthesias or numbness develops in the median nerve distribution.

Another test is that for Tinel’s sign, which is pain or paresthesias in the median nerve distribution elicited by light tapping or percussion over the median nerve at the wrist. Analysis of the literature suggests, however, that Tinel’s sign (sensitivity of 42 to 85%; specificity of 54 to 98%) is not as powerful as Phalen’s test in detecting median nerve compression, although neither is 100% sensitive.\textsuperscript{50} An additional test, Durkan’s compression test, which consists of application of pressure directly over the median nerve at the carpal tunnel, has a sensitivity of 87% and specificity of 90%.\textsuperscript{51}

Because none of these physical tests is completely reliable in making the diagnosis of carpal tunnel syndrome, nerve conduction studies have been used to confirm the diagnosis, with reports of 85 to 90% sensitivity.\textsuperscript{50} MRI and high-resolution ultrasound studies occasionally are used for confirmation, but the diagnosis of carpal tunnel syndrome is primarily clinical.\textsuperscript{51}

Conservative (nonoperative) treatment for carpal tunnel syndrome yields variable results. Specific measures include splinting the wrist in a neutral position and cortisone injections in the carpal tunnel. Splinting initially may be prescribed full time for 3 or 4 weeks and then reduced to splinting at night only. Kaplan identified five important factors in determining the success of nonoperative treatment: (1) age older than 50 years; (2) duration longer than 10 months; (3) constant paresthesias; (4) stenosing flexor tenosynovitis; and (5) positive Phalen’s test result at less than 30 seconds. Two thirds of patients in his series were cured by medical treatment when none of these factors were present. However, 59.6% with one factor, 83.3% with two factors, and 93.2% with three factors did not improve. No patient with four or five factors was cured by medical management.\textsuperscript{52} Nonsteroidal anti-inflammatory drugs have proved to be of little benefit. Surgical release of the flexor retinaculum to unroof the carpal tunnel is indicated when nonoperative management fails.\textsuperscript{55,54}

■ PERSPECTIVE

Accurate evaluation of forearm injuries requires a thorough knowledge of the complex anatomic relationships between the radius and the ulna. The ulna may be thought of as a stable structure around which the radius rotates, allowing supination and pronation to occur. With any injury to the forearm, the clinician should suspect an associated injury involving the elbow or wrist joints. The clinical and radiologic evaluation of
forearm injuries should include the wrist and elbow. The biomechanical interdependence of the radius and the ulna means that accurate reduction and fixation of forearm fractures will be essential to maintain full pronation and supination. Longitudinal rupture of the interosseous membrane that joins the diaphyseal shafts of the radius and ulna is known as the Essex-Lopresti lesion. This condition renders the forearm unstable, painful, and weak. It is difficult to diagnose because the plain radiographic appearance is essentially normal, and MRI is the diagnostic modality of choice.

Anatomy

The bones of the forearm consist of the radius and the ulna, which articulate at each end at the proximal radioulnar joint and the DRUJ. The capsule of the elbow joint and the annular ligament provide soft tissue support at the proximal articulation. Distally, the anterior and posterior radioulnar ligaments and the triangular fibrocartilage complex support the radioulnar joint. Of all of these soft tissue supports, the triangular fibrocartilage complex acts as the major stabilizer of the DRUJ. The interosseous membrane and the supinator, pronator teres, and pronator quadratus muscles join the shafts of the radius and ulna. These muscles act as important supports to the radial and ulnar shafts and are responsible for the significant bone displacement seen with some forearm fractures.

The forearm is divided into two compartments, one volar to the forearm bones and interosseous membrane and one dorsal, and the antebrachial fascia encloses each compartment. The volar compartment contains the flexors and pronators of the wrist and hand, and the dorsal compartment contains the extensor muscles of the wrist and hand. The muscles of each compartment are divided further into a superficial and a deep layer. The nerves and vessels of each compartment lie between the superficial and the deep muscle layers (Table 48-4).

Physical examination includes inspection of the injured forearm, taking note of any deformity or discoloration or lacerations of the overlying skin. Observation of the patient’s attempts at range of motion at the wrist and elbow joints is important, and results can be compared with range of motion of the “normal” uninjured side. The site of maximal tenderness should be determined by palpation along the entire length of the radius and ulna and by palpation of the soft tissues over the dorsal and volar surfaces of the forearm. The neurovascular examination of the forearm should include evaluation of the brachial artery pulse proximally and the radial and ulnar pulses distally and an assessment of distal radial, median, and ulnar nerve function.

**DIAGNOSTIC STRATEGIES: RADIOLOGY**

The routine radiographic views of the forearm are anteroposterior and lateral views and should include the wrist and elbow joints. The inclusion of the joint above and below the forearm is crucial because a fracture or dislocation at one end may be associated with a similar abnormality at the opposite end. The normal anatomic relationships between the distal radius and ulna, including the radial length measurement, the normal volar tilt of the radius, and the ulnar slant of the distal radial articular surface, are described in the section on radiology of the wrist (see Fig. 48-4). These same relationships are visible on the anteroposterior view of the forearm. The normal proximal radial alignment is seen best on the lateral view of the forearm, on which a line drawn through the proximal radial shaft and radial head should intersect the capitellum (Fig. 48-28). This radial line alignment is particularly important to assess in looking for the presence of a radial head dislocation.

Observing the orientation of several bony projections of the radius and ulna assesses normal alignment of the radial and ulnar shafts. On the normal anteroposterior view, the radial styloid should point in a radial direction, and the biceps tuberosity of the proximal radius should point in an ulnar direction. On the normal lateral view, the ulnar styloid should point dorsally, and the coronoid process of the proximal ulna should...
Forearm, with pain and swelling at the fracture site. All movements of the forearm and hand are resisted because of pain. A neurovascular examination is indicated to rule out associated neurologic impairment or early compartment syndrome. Anteroposterior and lateral radiographs of the forearm must include elbow and wrist joints to exclude an associated dislocation or articular fracture. Although these fractures usually are obvious on clinical examination, plain radiography constitutes an accurate means of determining the amount of fracture displacement and comminution.

Undisplaced fractures are rare in adults, but when they do occur, they are treated conservatively with immobilization in a long arm cast for a minimum of 8 weeks. Prompt orthopedic follow-up evaluation and repeat radiographs should be arranged within 1 week of injury to ensure that displacement did not occur after casting. Displaced fractures of the radial and ulnar shafts are treated surgically, with application of an appropriate splint, and an orthopedic referral should be obtained for open reduction and internal fixation. Fracture healing usually is complete in 6 months. Nonunion and malunion may occur in 3 to 5% of cases. The most significant complication of this fracture is a compartment syndrome, which may result from the initial trauma or develop after surgery.

**Ulnar Shaft Fractures**

Isolated ulnar shaft fractures, or “nightstick fractures,” are relatively common and usually are caused by a direct blow to the forearm. Patients have localized pain and swelling over the site of the fracture. Radiographs of the forearm show this fracture and depict the degree of fracture displacement if present.

Undisplaced fractures of the distal third of the ulna may be treated with immobilization in a short arm cast for 6 to 8 weeks. Fractures of the middle or proximal third of the ulna require long arm cast immobilization. Weekly follow-up monitoring is recommended to confirm continued lack of displacement during the period of fracture healing. If loss of fracture position occurs, open reduction and internal fixation are necessary.

Displaced fractures of the ulna are defined as fractures with more than 10 degrees of angulation or fractures with displacement greater than 50% of the diameter of the ulna. Whenever significant displacement is present, radiographs should be examined carefully to rule out an associated dislocation of the radial head (Monteggia's fracture). Patients with isolated displaced ulnar shaft fractures should be referred to an orthopedic surgeon for open reduction and internal fixation. Most fractures heal uneventfully, with excellent results. Fractures of the middle third of the shaft may be complicated by nonunion if adequate reduction is not achieved or maintained.

**Monteggia’s Fracture**

In 1814, Monteggia described a fracture at the junction of the proximal and middle thirds of the ulna associated with anterior dislocation of the proximal radial head. This original description accounts for only 60 to 65% of proximal ulnar fractures with associated radial head dislocation. The entire spectrum of fracture-dislocations has since been classified by Bado into four types of Monteggia lesions, depending on the site of the proximal ulnar fracture and the direction of fracture angulation and associated radial head dislocation. Overall, this injury is rare and accounts for only 1 to 2% of all fractures of the radius and ulna.

The mechanism of injury of Monteggia’s fracture is forced pronation of the forearm during a fall on the outstretched hand.
or a direct blow to the posterior aspect of the ulna. On clinical examination, pain and tenderness are present at the fracture site, and range of motion is limited at the elbow joint. The forearm may appear shortened compared with the unaffected side, and the radial head dislocation may be palpable in the antecubital fossa. A complete neurovascular examination is essential to rule out an associated radial nerve injury, which may be present in 3 to 70% of cases, although almost all of these neuropathies heal spontaneously.53

The proximal ulnar fracture is readily seen on anteroposterior and lateral radiographs of the forearm, but the elbow joint must be examined carefully to avoid missing the associated radial head dislocation (Fig. 48-30). This dislocation is commonly missed, and delayed diagnosis has been reported in 24% of cases.64 To avoid overlooking the associated radial head dislocation, the alignment should be confirmed on anteroposterior and lateral radiographs. A line drawn through the radial shaft and head on these views normally should intersect the capitellum on all views.

Treatment of Monteggia’s fracture is surgical, and immediate orthopedic referral should be arranged for definitive open reduction and internal fixation. An exception may be made in a pediatric patient, in whom closed reduction followed by a long arm cast may be effective. Casts should be in a flexed and supinated position to maintain fracture position. Flexion of the elbow should be as close to 90 degrees as possible while ensuring the maintenance of a good radial pulse. Common complications include malunion or nonunion of the ulna fracture with redislocation or subluxation of the radial head. These complications are more likely to occur when the diagnosis has been delayed or when fracture fixation has been inadequate.64

Galeazzi’s Fracture

Galeazzi’s fracture involves the junction of the middle and distal thirds of the radius, with an associated dislocation or subluxation of the DRUJ. This rare injury accounts for only 3 to 7% of all fractures of the forearm. Galeazzi’s fracture typically results from a fall on the outstretched hand, with the wrist in extension and the forearm forcibly pronated. Another less common but well-described mechanism of injury is a direct blow to the dorsoradial aspect of the wrist. Clinical examination often is the key to diagnosis, because disruption of the DRUJ may not be apparent otherwise. The radial fracture causes obvious swelling and deformity on the radial side of the forearm, and pain is localized over the fracture site. In addition, the DRUJ is swollen and painful on palpation, and the ulnar head appears prominent compared with the unaffected wrist.

On the anteroposterior radiograph, a transverse or short oblique fracture of the radius is visible at the junction of the middle and distal thirds of the radius. The radius appears shortened, and an increase in joint space may be visible between the distal radius and ulna. The lateral view shows dorsal angulation of the radial fracture, and the head of the ulna is displaced dorsally (Fig. 48-31). An associated ulnar styloid fracture is seen in approximately 60% of cases and should alert the physician to the presence of disruption of the DRUJ.65

Galeazzi’s fractures are inherently unstable. Occasionally, if the radial fracture is distal, a closed reduction of the radius and reduction of the DRUJ in supination with a long arm cast can be successful. However, less than 10% of patients have a good outcome with closed treatment—accordingly, the term “fracture of necessity” has been used to describe Galeazzi fractures, implying that operative repair is mandatory.66 The instability is the result of several factors, including the distracting pull of the brachioradialis and pronator quadratus muscles and the associated disruption of the DRUJ.

Figure 48-30. Monteggia’s fracture-dislocation. Fractures of the ulna diaphysis, with anterior angulation and associated anterior dislocation of the radial head, can be seen on this lateral radiographic view. (From Propp DA, Chin H: Forearm and wrist radiology—Part J. J Emerg Med 7:393, 1989.)

Figure 48-31. Galeazzi’s fracture-dislocation. The radiographs (left, anteroposterior view; right, lateral view) show an obvious fracture of the distal third of the radius with severe displacement and an associated dislocation of the distal radioulnar joint (arrow). (From Harris JH, et al: The Radiology of Emergency Medicine, 3rd ed. Baltimore, Williams & Wilkins, 1993.)
Operative treatment involves open reduction and internal fixation of the radial shaft fracture, with immobilization of the forearm in supination to maintain reduction of the DRUJ. Reports have suggested that failure of closed reduction of the DRUJ in some patients is due to soft tissue interposition, and in these cases open reduction and fixation of the DRUJ is recommended.\(^6^7\)

Complications of Galeazzi’s fracture include malunion and nonunion of the radial fracture and recurrent subluxation or dislocation of the DRUJ. These complications result in chronic pain, with significant limitation of pronation and supination, and are thought to be largely avoidable with appropriate open anatomic reduction and rigid internal fixation of the fracture.\(^6^8,6^9\)

**Pediatric Forearm Fractures**

**Shaft Fractures of Radius and Ulna**

In children, fractures to both bones of the forearm usually occur as a result of a fall on the outstretched hand. Fractures generally are classified into three types: buckle, or torus, fractures; incomplete, or greenstick, fractures; and complete fractures. The forearm fracture usually is obvious clinically, with significant pain, swelling, and visible deformity at the fracture site. Anteroposterior and lateral radiographs of the forearm distinguish whether fractures are complete or incomplete and show the degree of angulation and rotational deformity (Fig. 48-32).

The objective of successful treatment of forearm fractures in children does not differ significantly from treatment in adults; the goal is successful reduction of fracture deformity. Nevertheless, in children, an important consideration is the potential for spontaneous correction of residual fracture angulation with bone remodeling. The younger the child (especially younger than 10 years of age), and the closer the fracture is to the growth plate, the greater the potential for remodeling. These principles govern the acceptability of fracture reduction, and generally, angulation of less than 10 degrees is considered acceptable.\(^7^0\)

Greenstick and complete forearm fractures require orthopedic referral for closed reduction with the patient under deep procedural sedation or general anesthesia. Results usually are excellent if correction of angular and rotational deformity is achieved and maintained. Immobilization in a long arm cast usually is necessary for 7 to 8 weeks. Open reduction and internal fixation occasionally are necessary if closed reduction is unsuccessful or if correction cannot be maintained with casting. Complications of malunion and nonunion are rarely seen because of rapid healing and a tremendous capacity for remodeling in this population.\(^4^5\)

**Plastic Deformation**

The occurrence of plastic deformation of bone is unique to children and refers to a bending of the bone without overt fracture. Plastic deformation may be seen as an isolated injury to the radius or ulna, or it may be seen in one bone in combination with a fracture of the other bone. Clinically, this injury produces localized pain and deformity of the forearm, and radiographically, it appears as a fixed curvature of the bone shaft (Fig. 48-33). If significant curvature is present, the deformity is obvious, and pronation and supination are significantly restricted. Treatment requires orthopedic referral for closed reduction with the patient under general anesthesia and immobilization in a long arm cast for 6 to 8 weeks.\(^7^1\)
### KEY CONCEPTS

- Plain radiographs fail to detect 15% of scaphoid fractures. For this reason, and because of the associated risk of nonunion when diagnosis and immobilization are delayed, patients clinically suspected of having a scaphoid fracture should undergo CT scan or MRI for diagnosis of occult fracture.
- Triquetral fracture is best seen on the standard lateral view of the wrist as a small dorsal chip fragment, although a more oblique pronated lateral view may be necessary.
- Lunate dislocation results in a characteristic triangular appearance of the lunate on the posteroanterior view (piece of pie sign) due to the rotation of the lunate in a volar direction. This rotation also is visible on the lateral view of the wrist, on which the lunate looks like a cup tipped forward and spilling its contents into the palm (spilled teacup sign).
- In carpal dislocations, the articular surfaces on the posteroanterior view form three parallel arcs. The articular surfaces between carpal bones are parallel and 1 to 2 mm apart (parallelism).
- Colles’ fracture requires prompt anatomic reduction in the emergency department, with full restoration of radial length and correction of the dorsal angulation either to a neutral position or, ideally, to the normal volar tilt position. Closed reduction, using local or regional anesthesia, with cast immobilization is successful in most cases.
- Anteroposterior and lateral views of the forearm must include the wrist and elbow joints because radial and ulnar forearm fractures may be associated with proximal, radial, or DRUJ dislocations.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Injuries in the region of the elbow have a high potential for complications and residual disability. Early recognition of neurovascular and soft tissue complications improves the outcome in many of these injuries.

Anatomy

The humerus is a long bone that articulates proximally, at the shoulder, with the glenoid of the scapula to form the glenohumeral joint and distally with the radius and ulna to form the three-way elbow joint. The upper end of the humerus, the humeral head, is shaped like a near-hemisphere. Adjacent to the humeral head are two bony prominences, the greater and lesser tuberosities. Between these, on the anterolateral aspect of the humerus, runs the bicipital groove. The shaft of the humerus extends from the upper border of the insertion of the pectoralis major muscle superiorly to the supracondylar ridges inferiorly. The shaft is cylindrical on cross section in the upper half and tends to become flat in the distal portion in an antero-posterior direction. Three surfaces are described. The anterolateral surface presents the deltoid tuberosity for the insertion of the deltoid muscle, and below this is the radial soleus, which transmits the radial nerve and profunda artery. The anteromedial surface forms the floor of the intertubercular groove, but it normally has no outstanding surface markings. An exception is when the supracondylar process is present. The posterior surface is the origin for the triceps and contains the spiral groove.

The bony anatomy of the distal humerus and elbow is diagrammed in Figure 49-1. The distal end of the humerus tapers into two columns of bone, the medial and lateral condyles. Between the condyles, the bone thins, and the recess created is the coronoid fossa. The more proximal nonarticular portions of the condyles are the epicondyles. Just proximal to the epicondyles, the supracondylar ridges run up each side of the humerus. Collectively, these areas serve as points of origin for the muscles of the forearm. The wrist flexors originate from the medial epicondyle, and the wrist extensors originate from the lateral epicondyle. Fractures of the distal humerus often result in fragment displacement because of the pull of these strong forearm muscles on attachment sites.

The bony anatomy of the elbow allows for two complex motions: flexion-extension and pronation-supination. The elbow is composed of three articulations within a common joint cavity. The trochlea is the articular surface of the medial condyle and articulates with the deep trochlear notch of the ulna formed by the olecranon inferiorly and posteriorly and by the coronoid process anteriorly. This articulation permits hinged flexion and extension at the elbow. The articular surface of the lateral condyle is the capitellum, which permits the radius to hinge on the elbow. The proximal radius consists of a disklike head supported by the smooth narrow radial neck. The radial head articulates with the capitellum of the humerus and with the radial notch of the ulna.

Four ligamentous structures are important in evaluating elbow injuries (Fig. 49-2). The radial head is held in place by the annular ligament and the radial collateral ligament. Rotation of the radial head within the annular ligament permits pronation and supination. In addition, the ulnar collateral ligament and anterior capsule add stability to the joint. These structures may be severely damaged from fracture or dislocation of the joint.

The soft tissues of the upper arm are divided into two compartments: anterior and posterior. The anterior compartment contains three muscles—the biceps brachii, the brachialis, and the coracobrachialis—and the brachial artery, median nerve, musculocutaneous nerve, and median nerve. The only two structures contained in the posterior compartment are the triceps brachii muscles and the radial nerve.

The neurovascular structures of this area are diagrammed in Figure 49-3. The brachial artery, the continuation of the axillary artery, travels with the median nerve in the anterior compartment of the upper arm. It enters the antebrachial fossa as diagrammed and bifurcates into the radial and ulnar arteries.

The median nerve runs with the brachial artery as shown. One important anatomic variation is the presence of a supracondylar process (in approximately 2.5% of cases) just proximal to the medial epicondyle (Fig. 49-4). When the supracondylar process is present, the median nerve and brachial artery must traverse behind this process, then forward between a fibrous band connecting the process to the epicondyle. Median nerve symptoms may develop if this process is fractured or if an injury causes swelling in the vicinity of the supracondylar process.

The radial nerve leaves the axilla and spirals posteriorly around the humerus between the heads of the triceps in the radial groove. It reenters the anterior compartment of the arm laterally, crossing the elbow anterior to the lateral epicondyle to innervate the extensors of the wrist and fingers. Because of its close relationship to the shaft of the humerus, the radial nerve is particularly susceptible to injury with fractures of the midshaft of the humerus. Fixed in position by the intermuscular septum, the nerve may become trapped between fracture fragments, particularly when reduction is attempted.

The ulnar nerve runs parallel to the median nerve. Halfway down the arm, it penetrates the intermuscular septum to run
Figure 49-1. Bony anatomy of distal humerus and elbow region.

Figure 49-3. Neurovascular structures of elbow region. Volar surface of left elbow is shown.

Figure 49-4. Supracondylar process of the humerus (arrow). Volar surface of right elbow is shown.
along the medial aspect of the triceps muscle in the posterior compartment. It enters the forearm by passing behind the medial condyle. Fractures in the vicinity of the medial condyle place this nerve at considerable risk for injury.

Three elbow bursae are clinically important. The olecranon bursa is located between the olecranon and the skin posterior to the joint. This bursa provides protective padding and allows smooth movement of the skin over the olecranon. Because of its position, it is often a site of traumatic or infectious bursitis. The radiohumeral bursa provides for smooth movement over the radial head with supination and pronation. A third bursa cushions the biceps tendon from the radius during flexion of the elbow. As evident by the descriptions of these structures, all are vulnerable when significant skeletal injury occurs in this region.

### CLINICAL FEATURES

#### History

A history detailing musculoskeletal complaints includes a description of any pain in terms of quality, duration, location, palliative and provocative activities, severity, and radiation. Past medical history and occupational factors are important in chronic problems. For traumatic injuries, a complete account of the incident is important because it provides information about the mechanism of injury and some estimate of the energy delivered. Subjective complaints of numbness or weakness distal to the injury are important clues to possible neurovascular injury. In dealing with injuries in children, the possibility of child abuse must be considered.

#### Physical Examination

Inspection of the upper extremity is important, but manipulation of the painful extremity should be minimized and postponed to the end of the examination when possible. This is especially important with children. A great deal of useful information can be gathered by simple inspection and comparison with the contralateral limb. The position in which the extremity is held should be noted. Children with extension-type supracondylar fractures present with the arm held at the side with a characteristic S-shaped configuration, whereas with flexion-type supracondylar fractures, the forearm is supported with the opposite hand with the elbow flexed to 90 degrees. Patients with radial head subluxation have the elbow only slightly flexed and hold the forearm in pronation.

Deformity is evidence not only of significant injury, but also of the type of injury. Increased prominence of the olecranon suggests a posterior dislocation of the elbow or extension supracondylar fracture, whereas loss of the normal olecranon prominence indicates anterior dislocation or flexion supracondylar fracture. The extremity also should be inspected for wounds that may indicate an open fracture, evidence of swelling, and change in color of the distal extremity.

One special aspect of the elbow examination is the determination of the carrying angle, the normal outward angulation of the extended forearm at the elbow. This angle allows the long axes of the humerus and forearm to become superimposed when the elbow is flexed (Fig. 49-5). This angle varies from 5 to 20 degrees in adults, with men having less angulation than women. Measurement of the carrying angle is helpful in minimizing the normal olecranon prominence and documenting. With the forearm supinated, the normal range of motion is 0 degrees in full extension to 150 degrees in full flexion. A mild degree of hyperextension is normal in
some individuals and should be symmetrical. With the elbow flexed at 90 degrees and the thumb facing up, the forearm normally supinates and pronates 90 degrees. Range-of-motion testing may be impossible with severe injuries and can be postponed until after radiographic evaluation, avoiding manipulating fractures and dislocations. Any manipulation of the extremity must be followed by reexamination because neurovascular injury has been reported with nearly every therapeutic procedure.

**Radiographic Findings**

It is not necessary to obtain radiographs in all cases. Although clinical decision rules for the elbow have not been validated, it is reasonable to perform radiography when there is significant limitation in range of motion, obvious deformity, joint effusion, or significant tenderness over any of the bony prominences or the radial head. In the absence of these, it seems appropriate to omit radiography. The threshold for radiography should be much lower in pediatric populations due to the presence of open growth plates and limitation in the physical exam.

Routine views of the elbow include at least the anteroposterior and lateral views, with consideration given to obtaining oblique views for certain injuries. Anteroposterior and oblique views are taken with the elbow extended. The lateral view is taken with the elbow in 90 degrees of flexion and the thumb pointing upward. Positioning of the elbow is important because anything but a true lateral view makes accurate interpretation of soft tissue findings and alignment difficult. Corresponding views of the opposite extremity may be helpful, especially for children, but should not be ordered routinely.

Many fractures in the elbow region are obvious on plain film, with cortical disruption, angulation, or displacement of fragments. Minor fractures can be subtle and may be missed. Special attention to the contour of the radial head and the fat pads reduces the risk of missing fractures. The normal cortex of the radius is smooth and has a gentle continuous concave sweep. If consistent with history and physical findings, any disruption of this smooth arc is considered evidence of fracture. Abnormalities within the soft tissues on elbow films are particularly important and may be the only radiographic sign of a fracture. Normally, fat surrounding the proximal elbow joint is hidden in the concavity of the olecranon and coronoid fossae. The radiographically normal elbow has only a narrow strip of lucency anteriorly (the anterior fat pad), and a posterior fat pad is not visible. Injuries that produce intra-articular hemorrhage cause distention of the synovium and displace the fat out of the fossa, making the posterior fat pad visible on lateral radiographic views. The anterior fat pad also is altered by this swelling, becoming more prominent and taking the shape of a spinnaker sail from a boat: “sail sign” (Fig. 49-7). In the setting of trauma, more than 90% of patients with the “posterior fat pad” sign have intra-articular skeletal injury. These soft tissue findings occur even with subtle fractures, and when present in the setting of trauma, an occult fracture is considered to be present even when not visible on radiograph. In adults, a radial head fracture is implied, whereas in children, a supracondylar fracture is the probable underlying injury. In the absence of trauma, the presence of a fat pad suggests other causes of effusion (e.g., gout, infection, bursitis). The fat pad sign may be absent with a fracture if the injury is severe enough to have ruptured the capsule.

The anterior humeral line is a line drawn on a lateral radiograph along the anterior surface of the humerus through the elbow. Normally this line transects the middle third of the capitellum (Fig. 49-8). With an extension supracondylar fracture, this line either transects the anterior third of the capitellum or passes entirely anterior to it. The abnormal relationship between the anterior-humeral line and capitellum may be the only evidence of a minimally displaced supracondylar fracture.

Another diagnostic aid in evaluating radiographs of possible supracondylar fractures in children is the determination of Baumann’s angle. As shown in Figure 49-9, the intersection of a line drawn on the anteroposterior film through the midshaft of the humerus and the growth plate of the capitellum defines an angle of approximately 75 degrees. In normal children, Baumann’s angle is the same in both elbows, and it has been suggested that a comparison between the injured and uninjured sides be used to assess the accuracy of reduction. An increase in Baumann’s angle indicates medial tilting of the distal fragment. Alteration in Baumann’s angle is thought to predict the final carrying angle when the fracture heals, although there is controversy regarding its reliability.

Radiographic evaluation of the elbow in children is difficult because of the presence of multiple ossification centers (Fig. 49-10). Table 49-1 lists the typical age of first appearance

![Figure 49-6](image-url)
Figure 49-7. A, Anterior and posterior fat pads seen on lateral study (arrow). B, The anterior fat pad is normally a thin radiolucent stripe; the posterior fat pad is now seen. C, An effusion displaces both fat pads. This posterior fat pad is now visible.

Figure 49-8. A, A line drawn down the anterior surface of the humerus on a lateral film should transect the middle of the capitellum. B, With an extension supracondylar fracture, the line passes more anteriorly. (From Simon R, Koenigsknecht S: Emergency Orthopaedics: The Extremities, 2nd ed. Norwalk, Conn, Appleton & Lange, 1987.)

and fusion of ossification centers. Comparison views of the uninjured elbow are often helpful in distinguishing fractures from the normal epiphyses and ossification centers.

## Management

General management principles for humerus and elbow injuries are similar to those for other orthopedic injuries. Life-threatening conditions, such as vascular injury, must be addressed immediately by reduction of fractures or surgical exploration. The limb should be splinted in a position of comfort, and appropriate analgesia should be provided. Antibiotics are administered for suggested open fractures. Prolonged immobilization of the elbow frequently results in stiffness of the joint that requires extensive physiotherapy to restore normal function. For this reason, range-of-motion exercises are begun early in the convalescent period, often before a fracture has healed completely.

### FRACTURES

Injuries in the region of the shaft of the humerus and about the elbow fall into several categories (Box 49-1). Emergency department (ED) management varies with location and type of fracture or dislocation.

#### Fractures of the Shaft of the Humerus

**Pathophysiology**

Fractures of the humeral shaft commonly result from a direct blow to the arm, such as occurs during a fall or motor vehicle crash. Severe twisting of the arm or a fall on an outstretched hand can also produce this type of fracture. Fractures produced by violent muscle contraction, such as occur when throwing a javelin or baseball, also are reported. Motion of the humerus is controlled by several muscle groups, which also influence the fracture pattern of the humeral shaft. If the fracture is located proximal to the attachment of the pectoralis major, the proximal fragment of the humerus abducts and rotates internally owing to the action of the rotator cuff, whereas the distal fragment is displaced medially by the pectoralis major (Fig. 49-11A). If the fracture occurs below the pectoralis major insertion but above the deltoid insertion, the distal fragment is displaced laterally by the deltoid muscle, and the proximal fragment is displaced medially by the pull of the pectoralis major, latissimus dorsi, and teres major muscles (Fig. 49-11B). In fractures occurring distal to the deltoid insertion, the proximal fragment is abducted by the deltoid, and the distal fragment is proximally displaced (Fig. 49-11C). The shaft of the humerus most commonly fractures in the middle third in a transverse fashion (Fig. 49-12).

#### Clinical Features

The patient complains of localized pain. The arm is visibly swollen and cannot be used. When a fracture is complete, bony crepitus is felt in the shaft of the humerus with any manipulation of the arm. The arm may be shortened or rotated, depending on the displacement of the fracture fragments. When the fracture is incomplete, the skeleton is tender to palpation and swollen, but not otherwise deformed. A complete neurovascular examination is indicated. Attention should be directed to radial nerve function because injury to this nerve is the most common complication associated with humeral shaft fractures.

Radiographic findings are confirmatory. Studies routinely should include the shoulder and elbow joints. The humerus is a common site for benign tumors, unicameral cysts, and primary bone malignancies. The humeral shaft also is a common site for metastatic disease. Thinning of the cortex and abnormal osteoblastic or osteoclastic activity are evidence of a pathologic fracture (see Fig. 49-12). These fractures do not heal without concomitant treatment of the underlying pathologic condition.

#### Management

Closed fractures that are isolated injuries are treated conservatively with a high degree of success. Elaborate attempts at fracture reduction and external immobilization are unnecessary and sometimes detrimental to healing. Humeral shaft fractures remain surrounded by a richly vascularized envelope of muscle so that fracture reduction is accomplished most easily with the aid of gravity and muscle balance. Fractures that are nondisplaced or minimally displaced are immobilized by adding a coaptation, or “sugar-tong,” splint, to the sling and swathe (Fig. 49-13). This is accomplished by first padding the extremity, then carrying a long plaster splint from the lateral side of the shoulder, down the lateral aspect of the upper arm, around the elbow with the elbow flexed, and then up the inner aspect of the arm to the axilla. The sugar tong is wrapped in an elastic bandage, and a sling is used to support the arm in 90 degrees or less of flexion. The weight of the splint aided by gravity applies traction at the same time it immobilizes the fracture. Some authorities use the coaptation splint for only the first 10 to 14 days of treatment followed by a functional brace.

If the fracture is grossly displaced or comminuted, the hanging cast technique sometimes is used. This technique is especially effective with spiral fractures. The cast is light-
Figure 49-11. Influence of muscles on displacement of humeral shaft fractures based on fracture location. 

A, Fracture is proximal to the attachment of the pectoralis major muscle. B, Fracture is between insertion of the pectoralis major and deltoid muscles. C, Fracture is distal to the deltoid insertion.

weight, applied at least 1 inch proximal to the fracture site, and extends to the distal palmar crease of the hand. The elbow is flexed 90 degrees, and the wrist is placed in the neutral position. The sling is attached through a loop at the wrist. Angulation is corrected by placing the plaster loop on the dorsal aspect of the cast (to reduce lateral angulation) or on the volar side of the cast (to reduce medial angulation). Anterior or posterior angulation is corrected by altering the length of the sling apparatus (Fig. 49-14). Care must be taken not to make the cast too heavy because this would distract fracture fragments. The hanging cast has the disadvantage of requiring gravity for traction and requires that the patient remain upright at all times, including during sleep, a situation that many patients find intolerable. Neurovascular examination is repeated after the application of any splint or cast. Loss of nerve function from entrapment of the nerve between fragments can occur after these interventions.

Open reduction and internal fixation (Fig. 49-15) is necessary in certain circumstances, including open fractures, presence of multiple injuries that preclude mobilization, bilateral fractures, poor reduction, poor patient compliance, failure of closed treatment, and fractures through pathologic bone. Isolated radial nerve palsy usually is assumed to be a neurapraxia and is managed nonoperatively. Exploration and
internal fixation are indicated, however, if the radial nerve palsy develops after manipulation because this is highly suggestive of nerve entrapment. 4

All patients with humeral shaft fractures should be referred to an orthopedic surgeon for close follow-up monitoring. When dependency casting is used, follow-up evaluation within 24 to 48 hours is recommended to be certain that the alignment has been maintained. Emergent referral to an orthopedist is recommended for patients with evidence of radial nerve injury, severely displaced or comminuted fractures, open fractures, or fractures associated with forearm fractures in the same extremity.

Complications

The most common complication, radial nerve injury, occurs in 20% of humerus fractures. This nerve injury is most often a benign neurapraxia that resolves spontaneously in most patients, although recovery may take several months. Radial nerve injuries associated with penetrating trauma or open fractures are likely to be permanent and usually warrant operative exploration. Median and ulnar nerve injuries are rarely seen, usually in the presence of penetrating trauma. Injuries to the brachial artery occur rarely and, if clinically suggested, angiography or other vascular studies should be considered.

Fractures of the Distal Humerus

Supracondylar Fractures

Distal humerus fractures that occur proximal to the epicondyles are called supracondylar fractures. This fracture is almost exclusively an injury of the immature skeleton. The peak incidence is in children 5 to 10 years old; the average age in a large combined series was 6.7 years. 6 This injury rarely occurs after age 15 and accounts for approximately one half of all
elbow fractures and one third of pediatric limb fractures. In children, the tensile strength of the collateral ligaments and joint capsule of the elbow is greater than that of bone. In adults, the reverse is true, and a posterior elbow dislocation is sustained instead. Supracondylar fractures are classified as either extension or flexion fractures, depending on the mechanism of injury and the displacement of the distal fragment. Of these injuries, 98% are of the extension type.

Extension Supracondylar Fractures

Pathophysiology. Extension supracondylar fractures occur as a consequence of a fall on the outstretched arm, when the elbow is either fully extended or hyperextended (e.g., a fall off the “monkey bars”). The elbow is likely to be in the latter position at the time of the fall because ligamentous laxity, with hyperextension of the joints, is a normal phenomenon in younger children. With the forearm acting as a lever,7 the ground reaction produces a moment of force at the elbow (Fig. 49-16). Ultimately the distal humerus fails anteriorly in the supracondylar area. The strong action of the triceps tends to pull and displace the distal fragment in a posterior and proximal direction. There may be anterior angulation of the sharp distal end of the proximal fragment into the antecubital fossa, endangering the brachial artery and median nerve (Fig. 49-17). In most cases, however, the brachialis muscle protects the anterior neurovascular structures from injury.

Clinical Features. A child with a complete fracture comes to the ED holding the upper extremity immobile in extension to the side, with a typical S-shaped configuration and tenderness and swelling in the region of the elbow. Prominence of the olecranon attached to the posteriorly displaced distal fragment is similar to that seen with posterior dislocation of the elbow. When an incomplete supracondylar fracture exists, the diagnosis may be less obvious, with an elbow effusion as the only clinical sign. A careful neurovascular examination is essential. Although palpation is useful in determining the site of injury, the examining physician should avoid manipulation of the injury to elicit crepitus because movement can cause further neurovascular damage. Alleviating pain often facilitates the examination.

Diagnostic Strategies. On radiographic examination, the distal fragment is often displaced on the lateral view. This displacement is most likely to occur with a complete fracture wherein the muscle activity results in proximal migration of the distal fragment. Because this fracture occurs in children, 25% of supracondylar fractures are of the greenstick variety with the posterior cortex remaining intact. Subtle changes (e.g., the presence of a posterior fat pad or an abnormal anterior humeral line) may be the only radiographic clues to the presence of a fracture (Fig. 49-18). In displaced fractures on the anteroposterior view, the distal fragments may be displaced either medially or laterally in relationship to the humerus. Often, with minimally displaced fractures, the fracture line is transverse and not visible on the anteroposterior view. Based on radiographic findings, extension supracondylar fractures are classified into three types: type I, minimal or no displacement; type II, displaced fracture, posterior cortex intact; and type III, totally displaced fracture, anterior and posterior cortex disrupted.

Management. Nondisplaced fractures (type I) are immobilized primarily for comfort and protection because they are inherently stable. They are treated in a splint or cast flexed to 90 degrees with the forearm in neutral rotation. Protected active range of motion is begun in approximately 3 weeks. Even without definite radiographic findings, a child with localized tenderness consistent with a supracondylar fracture should be splinted and referred for follow-up examination. A radiographic study performed a few weeks after the injury may reveal periosteal new bone formation in the supracondylar region.

Minimally displaced (type II) fractures that are stable after reduction can be treated with splinting or casting with the elbow flexed. Some authors recommend flexion to 110 to 120 degrees for this injury.6,8,9 This position uses the intact posterior periosteum as a tension band to hold the reduction; however, if swelling or circulatory obstruction prevents this much flexion, it cannot and should not be used.
The greater the flexion at the elbow, the greater is the chance of vascular impairment. When swelling peaks at 24 to 48 hours, the risk of vascular obstruction and compartment syndrome is the greatest. Occasionally, these injuries must be pinned percutaneously to maintain stability, especially if a significant rotational component is present. Percutaneous pinning of a fracture after reduction has grown in popularity in recent years.10

Type III totally displaced fractures generally are the result of more severe injuries that produce more swelling than type I or type II injuries. Displacement necessitates the reestablishment of length, increases the chance of varus deformity, and increases the chances of interposed soft tissues and neurovascular injury. For all these reasons, patients with type III fractures require immediate orthopedic consultation in the ED and should be admitted to the hospital for frequent neurovascular checks and closed versus open fixation and percutaneous pinning.

These general principles should be adhered to in treating these injuries: (1) achieving adequate reduction, (2) properly assessing reduction, and (3) maintaining the reduction. Closed reduction is attempted with the patient under anesthesia. If closed reduction is not possible or if the brachial artery seems to be trapped in the fracture site, open reduction may be necessary. When adequate reduction has been achieved, most authorities recommend percutaneous pin fixation to maintain the reduction.7,11-13

Reduction in the ED is indicated only when the displaced fracture is associated with vascular compromise that threatens the viability of the extremity. Under these conditions, closed reduction should be attempted. After appropriate procedural sedation, an assistant fixes the arm of the patient. The physician grasps the patient’s wrist and applies steady, firm traction in line with the long axis of the limb (Fig. 49-19A). The forearm is kept in the neutral, thumb-up position. While traction is maintained, correction of any medial or lateral displacement is accomplished with the other hand at the elbow (Fig. 49-19B). If the distal fragment is displaced laterally, it is pushed inward; if it is displaced medially, it is pushed outward.

After length is restored and the angular deformity is corrected, the thumb of the free hand is placed over the anterior surface of the proximal fragment with the fingers behind the olecranon. While traction is maintained, the elbow is gently flexed to just beyond 90 degrees (Fig. 49-19C). Angulation is corrected to a normal carrying angle.
Medially displaced supracondylar fractures are most prone to tilt into cubitus varus and are immobilized with the forearm pronated to tighten the brachioradialis and common extensor muscles. This procedure closes the fracture laterally. The less common laterally displaced fracture is immobilized in supination to close the fracture medially.

Only one attempt should be made at manipulation. Multiple attempts increase the likelihood of neurovascular injury and swelling. If reduction is unsuccessful, simple traction on the extended elbow may restore vascular supply. When reduction is performed, follow-up radiographs are obtained to ensure adequate reduction. Neurovascular function is checked at frequent intervals. Cylinder casts are not applied initially because they increase the risk of forearm ischemia; a posterior plaster splint provides safe and adequate immobilization.

Patients with type I fractures can be discharged safely from the ED with instructions to elevate the extremity and apply ice and have a follow-up evaluation in 1 to 2 days. Fractures that require manipulation usually warrant admission to the hospital to ensure compliance and for neurovascular monitoring.

Complications. Ten percent of children lose the radial pulse temporarily, most often as a result of swelling and not direct brachial artery injury. Reducing the fracture, avoiding flexing the elbow more than 90 degrees, and elevating the arm help prevent secondary obstruction to arterial flow. Compartment syndrome, or Volkmann’s ischemic contracture as a result of prolonged ischemia of the forearm, is a dreaded complication but is rare in this era (reported incidence < 0.5%).

The most common complication is the loss of the carrying angle, resulting in a cubitus varus, or “gunstock,” deformity.
Measurement of Baumann’s angle after reduction is predictive of the final carrying angle. Cubitus varus has been reported previously in 25 to 60% of patients, depending on the treatment method used. This incidence has decreased significantly (<10%), with the use of percutaneous pinning. The distal humerus has little capacity to remodel because only 20% of the growth of the bone derives from the distal physis. A small amount of extension or flexion deformity produces little disability, has the greatest chance of remodeling, and is not a major cosmetic concern. Valgus or varus deformities, being in the coronal plane, have little or no chance of remodeling. Although cubitus varus is not a significant functional disability, it presents a significant cosmetic problem. In most cases, this complication can be corrected at a later time by an osteotomy. Nerve injuries occurred in 7% of 4520 fractures compiled from 31 major reported series. The incidence increases to a range of 19 to 49% with increasing severity of fracture displacement. The radial, median, and ulnar nerves all are commonly involved. Most deficits seen at the time of injury are neurapraxias that resolve with conservative management. Motor function returns within 7 to 12 weeks, whereas recovery of sensation may take more than 6 months.

**Flexion Supracondylar Fractures**

**Pathophysiology.** Flexion-type injuries are much less common, with a reported frequency of 1 to 10%; they account for 2% of all supracondylar fractures in a large pooled series of 7212 patients. The mechanism of injury is a direct blow to the flexed elbow. Energy is transferred from the posterior aspect of the proximal ulna to the distal humerus, resulting in a supracondylar fracture with anterior displacement of the distal fragment. As the fragment displaces, the periosteum is torn posteriorly.

**Clinical and Radiographic Features.** The elbow is usually held in flexion rather than the extremity presenting in the S-shaped configuration seen in extension-type injuries. In displaced fractures, the normal olecranon process is not palpable, in contrast to the increased prominence of the olecranon seen with extension injuries. Radiographically, these injuries can be classified into three types, similar to extension injuries:

- **Type I fracture**—undisplaced or minimally displaced
- **Type II fracture**—incomplete fracture; anterior cortex intact
- **Type III fracture**—completely displaced; distal fragment migrates proximally and anteriorly

Plain films may reveal a simple increase in the anterior angulation of the distal supracondylar fragment or gross displacement of the distal fragment proximal and anterior to the distal end of the proximal fragment. In the latter case, the distal end of the proximal fragment protrudes posteriorly. A line drawn through the anterior humeral shaft intersects the capitellum either normally or posteriorly in these fractures, depending on whether there is anterior displacement.

**Management.** When the posterior periosteum is torn, the anterior periosteum functions as a tension band with the arm in extension. In type I fracture, the periosteum is minimally displaced. These injuries do not need to be immobilized in extension. The elbow can be comfortably flexed and should be immobilized in a splint as with extension injuries. Type II and III injuries should be referred to an orthopedist emergently. Type II injuries are manipulated into extension, then held either in a long arm cast or with percutaneous pins. Type III injuries often require open reduction (Fig. 49-20).

**Complications.** The most common complication is injury to the ulnar nerve by the proximal fragment. The radial and median nerves are rarely injured. Stiffness of the elbow also may occur, especially after open reduction. Cubitus valgus may occur, but is not as cosmetically problematic as cubitus varus.

**Transcondylar Fractures**

Transcondylar (or dicondylar) fractures have a fracture line, either transverse or crescent-shaped, that passes through both condyles within the joint capsule just proximal to the articular surface (Fig. 49-21). As with supracondylar fractures, two types have been described—extension and flexion—based on the position of the elbow when fractured. Extension types are the most common. The mechanism of injury is similar to that for supracondylar injuries. In contrast to supracondylar fractures, however, the injury is more common in elderly individuals with fragile, osteoporotic bone. These fractures generally are difficult to treat because the small distal fragment possesses little extra-articular bone, and only a small amount of bone contact is available for union. During healing, excessive callus may form in the olecranon or coronoid fossae with residual loss of motion. Orthopedic consultation should be immediately obtained for these injuries.

**Intercondylar Fractures**

Intercondylar fractures are usually T-shaped or Y-shaped fractures with variable degrees of separation of the condyles from each other and from the proximal humerus fragment (Fig. 49-22). The distal portion of the fracture extends to the articular surface of the distal humerus. These injuries are rare and generally are seen in adults in their 50s and 60s. The usual mechanism of injury is direct trauma to the elbow that drives the olecranon against the humeral articular surface and splits the distal end.

**Clinical and Radiographic Features.** Patients with intercondylar fractures complain of pain at the elbow, which on examination is
tender to palpation. Good-quality anteroposterior and lateral radiographic views are essential in evaluating fracture displacement and comminution (Fig. 49-23). Computed tomography may be used to delineate fracture patterns further. Neurovascular complications are not common with these injuries.

Management. Intercondylar fractures are notoriously difficult and complicated to treat.20,21 The goal of treatment is to reestablish articular congruity and alignment and to begin active motion as soon as possible. Open reduction with rigid internal fixation is usually preferred. Closed treatment has been recommended for elderly patients, for patients with medical conditions that prohibit surgery, and historically for patients with nondisplaced fractures. These injuries all should be referred to an orthopedic surgeon emergently. Similar to supracondylar fractures, manipulation should be avoided, unless limb-threatening ischemia is present. Traction across the elbow with the arm extended is helpful in restoring blood flow to an ischemic forearm.

Complications. Historically, loss of elbow joint function is the most common complication reported, although this now can be largely avoided with optimal surgical technique.22 Any method of treatment that requires prolonged immobilization is likely to result in fibrosis or ankylosis of the joint. Neurovascular complications are rare.

Lateral Condyle Fractures in Children

Lateral condyle fractures are the second most common fractures involving the elbow in children, after supracondylar fractures.23 The fracture has a similar age distribution to a supracondylar fracture and occurs after a fall on the outstretched hand, with a varus stress applied to the extended arm.

Clinical and Radiographic Features. Tenderness and swelling are noted over the lateral aspect of the elbow. Generally, children exhibit less swelling than with supracondylar fractures, and neurovascular compromise is uncommon. Diagnosis is usually made on standard anteroposterior and lateral views, although an oblique view also may be helpful. These fractures are notoriously difficult to diagnose because fractures with minimal displacement are difficult to see radiographically and are often misdiagnosed as supracondylar humerus fractures.

Management. Nondisplaced fractures are treated nonoperatively with a cast, whereas fractures with any displacement require closed or open reduction with percutaneous pin fixation for 3 to 4 weeks.23,24

Complications. The risk for neurovascular compromise is much lower than that of supracondylar humerus fractures. Fractures diagnosed and treated in a timely manner should have few complications, although historically, nonunion, cubitus varus or valgus, and fishtail deformity (avascular necrosis) have been reported.23
Medial Condyle Fractures in Children

Medial condyle fractures are rare, constituting 1 to 2% of pediatric elbow fractures. These fractures are Type IV Salter-Harris injuries with physeal injury a possible outcome. The mechanism of injury is believed to be a valgus force on the extended elbow.

Clinical and Radiographic Features. The patient presents with tenderness and swelling over the medial aspect of the elbow. Anteroposterior, lateral, and oblique films may show the fracture in older children, but because the trochlea does not ossify until about age 9, plain films in younger children do not show the fracture. Magnetic resonance imaging (MRI) may be necessary to confirm the diagnosis in these patients.

Management. Operative treatment is indicated if displacement is greater than 2 mm; otherwise, conservative treatment is sufficient.

Complications. A study of 21 patients with medial condyle fractures revealed a 33% complication rate. Complications included loss of reduction requiring reoperation, avascular necrosis, nonunion, and cubitus varus. Most minimally displaced fractures healed uneventfully.

Condylar Fractures in Adults

Condylar fractures are rare in adults and typically involve the articular surface and the nonarticular portion of the distal humerus, including the epicondyle (Fig. 49-24). The status of the lateral trochlear ridge is the key to analyzing humeral condylar fractures. It may be involved with either medial or lateral condylar fractures and, when incorporated into the distal fragment, is far more likely to result in instability.

Pathophysiology. Lateral condylar fractures are uncommon, although more common than those of the medial condyle. The mechanism of injury is either a direct blow to the lateral aspect of the flexed elbow or a force that results in adduction and hyperextension with avulsion of the lateral condyle. Medial condylar fractures are rare and result from either a direct blow to the apex of the flexed elbow or a fall on the outstretched arm with the elbow forced into varus.

Clinical and Radiographic Features. The presentation of condylar fractures is similar to that of other distal humerus fractures, with swelling, tenderness, and crepitus localized over either the medial or the lateral elbow. On palpation, independent motion of the involved condyle may be appreciated. In lateral condylar fractures, findings may be accentuated with movement of the radius. On radiographic examination, lateral condylar fractures show a widening of the intercondylar distance. The distal fragment is often displaced, most commonly posteriorly and inferiorly. Because of the location of the ulnar nerve, it is imperative to test its function when this fracture is present. Medial condylar fractures are associated with tenderness over the medial condyle and pain with flexion of the wrist against resistance. On radiographic examination, displaced distal fragments tend to be anterior and inferior because of the pull of the forearm flexors.

Management. Immediate treatment depends on radiographic findings. For undisplaced or minimally displaced condylar fractures, immobilization of the flexed elbow in a long arm posterior plaster splint is sufficient. For lateral condylar fractures, the forearm should be supinated and the wrist extended to relieve the tension on the extensor muscle attachments. For medial condylar fractures, the reverse is true (i.e., the forearm should be pronated and the wrist flexed). For fractures displaced greater than 3 mm, surgical fixation is required.

Complications. Complications include nonunion, restricted range of motion, joint instability, cubitus valgus or varus deformity, arthritis, and ulnar neuropathy. Because of the high rate of complications, all condylar fractures should have orthopedic consultation.

Articular Surface Fractures

Capitellum Fractures

Pathophysiology. Although fractures of the capitellum and trochlea do occur as isolated injuries, more often they occur as a result of posterior dislocation of the elbow. Injury to the capitellum occurs when the patient falls on an outstretched hand, jamming the radial head upward, similar to a piston, shearing...
off the capitellum into the radial fossa. Because the capitellum has no muscular attachments, the fragment may remain non-displaced. More often, the fragment is displaced (usually anteriorly, but occasionally posteriorly). Because of this mechanism, a radial head fracture also may be present.

**Clinical and Radiographic Features.** The development of significant signs and symptoms may be delayed with capitellum fractures. Eventually, swelling within the capsule results in severe pain that manifests as well-localized tenderness on examination. Flexion of the elbow increases pain. A true lateral plain film usually shows the fragment lying anterior and proximal to the main portion of the capitellum (Fig. 49-25).

**Management.** Treatment begins in the ED with a posterior splint, ice packs, elevation, compression, and analgesia. Accurate anatomic alignment, rigid internal fixation, and early mobilization are prerequisites for a good functional result. Fractures of the articular surfaces can be treated nonsurgically only if radiographs show perfect anatomic alignment.

**Complications.** Complications include post-traumatic arthritis, avascular necrosis of the fracture fragment, and restricted range of motion.

**Trochlea Fractures**

**Pathophysiology.** Isolated fractures of the trochlea are exceedingly rare because of the structure’s protected position deep within the elbow joint. The shearing force of the ulna against the trochlea is associated more commonly with posterior elbow dislocation.

**Clinical Features.** The elbow is painful, with an effusion and limited range of motion because this is an intra-articular injury. On the radiograph, a fragment is seen lying on the medial side of the joint, just distal to the medial epicondyle, and signs of joint effusion are visible. The fracture may extend into the distal portion of the medial epicondyle.

**Management.** Nondisplaced fractures may be treated with a posterior splint for 3 weeks followed by early range-of-motion exercises. Displaced fractures should be treated operatively; fractures that can be internally fixed are repaired, whereas small fragments are excised. Immobilization should be minimized to 10 to 14 days.

**Epicondyle Fractures**

Most epicondylar fractures involve the medial epicondyle. Medial epicondyle fractures are most common in children and adolescents and often involve the apophysis, which is the last ossification center to fuse in the distal humerus, usually after age 15. Fractures through this ossification center usually occur in adolescence and constitute 11% of pediatric elbow fractures. These are not Salter-Harris injuries because the apophysis is involved rather than the physis. Because the lateral epicondyle is almost level with the flattened outer surface of the lateral condyle, it has only minimal exposure to a direct blow, and fracture is extremely rare.

**Pathophysiology.** Medial epicondyle injuries occur from a variety of mechanisms. First, avulsion fractures are associated with posterior elbow dislocations in patients younger than 20 years. Second, repetitive valgus stress (as with throwing a ball) results in eventual avulsion fracture of the epicondyle (Little League elbow). Another reported cause of fracture separation of the medial epicondyle, usually in adolescent boys, is from arm wrestling. Violent muscular forces associated with a shifting center of gravity during this activity seem to produce an avulsion just before closure of the epiphyseal plate. Finally, a direct blow to the medial epicondyle can cause this injury.

**Clinical and Radiographic Features.** The elbow is held in flexion, and any movement is resisted. Isolated fractures are associated with focal tenderness over the medial epicondyle. Use of the forearm flexors increases pain because their attachment is along the medial epicondyle. Ulnar nerve function should be evaluated. When associated with a posterior dislocation, the examination reveals a prominent olecranon.

Simple fractures of the medial epicondyle are extra-articular injuries with limited soft tissue injury. They generally do not produce a fat pad sign on the lateral radiographic view of the elbow. A posterior fat pad or significant swelling of the joint should suggest concurrent injuries, such as elbow dislocation. Careful radiographic evaluation is especially important because fracture fragments may migrate into the joint space. If the fragment is overlying the joint line on radiographic examination, it should be considered intra-articular (Fig. 49-26). Radiographic detection of the intra-articular fragment is often difficult. Associated ulnar nerve palsy may be present with an entrapped fragment. Fragments may be difficult to see on radiographs, and a true anteroposterior view is difficult to obtain because of severe pain on extension. In an adolescent patient, there is a tendency to confuse the normal radiolucent epiphyseal growth plate with a fracture. Additionally, mini-
Little Leager’s Elbow

Little Leager’s elbow warrants special mention. An adolescent pitcher traumatizes immature epiphyses by repetitive throwing. Throwing the curve ball or breaking ball has been implicated as a particular culprit, although the most important factor appears to be the total number of pitches per game. It has been shown in a group of highly competitive young baseball players that this injury is also common in catchers and fielders. The adolescent bone structure cannot withstand the extreme loading produced by repetitive hard throwing. Avulsion of the medial epicondylo or compression fracture of the subchondral bone of the lateral condyle or radial head may result (Fig. 49-27). This diagnosis should be sought in an athletic adolescent with medial epicondylo or radial head pain in the absence of acute injury by history. Adolescents with this condition should be forced to rest the elbow if throwing causes pain. After healing occurs, the amount of throwing and technique should be monitored carefully. The Committee on Sports Medicine and Fitness of the American Academy of Pediatrics and Little League Baseball recommend preventive measures to avoid these injuries, especially in pitchers. The latest updates on new rules set forth by Little League Baseball can be found at www.littleleague.org.

Figure 49-27. Little league’s elbow. Avulsion fracture of medial epicondyle (1). Compression fractures of the radial head (2) and capitellum (3). (From Connolly JF: DePalma’s Management of Fractures and Dislocations. Philadelphia, WB Saunders, 1981.)
eral ligament commonly occur. Displacement of the radial head fragment suggests considerable force and significant soft tissue injury. This injury is characterized by localized tenderness over the radial head or pain with passive rotation of the forearm.

**Diagnostic Strategies.** Radiographic findings range from a subtle disruption of the usual gradual sweep of the radial neck and head surface to an obvious displaced or comminuted fracture (Fig. 49-29). Undisplaced fractures are notoriously difficult to see on radiographs. Tenderness coupled with a positive fat pad sign on radiograph should be treated as a radial head fracture even in the absence of a visible fracture. Radial head fractures are classified into four types:

- **Type I**—undisplaced fractures
- **Type II**—marginal fractures (involving <30% of the articular surface) with displacement, including impaction or angulation
- **Type III**—comminuted fractures of the entire radial head
- **Type IV**—any of the above with elbow dislocation

**Management.** Type I nondisplaced fractures are treated symptomatically by a brief period of sling support and early range-of-motion exercises (within 24–48 hours). Aspiration of the hemorrhrosis and injection of 0.5% bupivacaine into the joint space may give dramatic relief of pain and improve the range of motion. Most patients with this injury recover well in 2 to 3 months. A few do poorly, however, with long-term pain, contracture, or inflammation.

Type II injuries usually are treated similarly, with aspiration, instillation of bupivacaine, and immobilization in the ED, followed by a trial period of range-of-motion exercises. In these cases, aspiration of the joint and instillation of bupivacaine not only relieve pain, but also allow testing of the range of motion to identify entrapped fragments. Early excision is advised for type II fractures when a mechanical block is present and for most type III fractures. Long-term functional results after radial head excision are acceptable in most patients, although a few have some functional disability after this procedure. Type IV injuries are treated for the elbow dislocation as described next and for the specific radial head lesion.

### DISLOCATION AND SUBLUXATION

#### Elbow Dislocation

Because of its anatomic structure, the elbow is inherently subject to mechanical instability, and dislocations are common. The elbow is second only to the shoulder as the most commonly dislocated large joint. Elbow dislocation is a term usually used to describe a disruption of the relationship between the humerus and the olecranon. Generally the radius and ulna, bound together firmly by the annular ligament and interosseous...
ous membrane, displace as a unit. Most classifications refer to the abnormal position of the ulna relative to the humerus. The elbow most often dislocates posteriorly, although it may dislocate anteriorly, medially, or laterally (Fig. 49-30). A dislocation also may occur between the radius and ulna, and such dislocations rarely occur concurrently with the ulnohumeral type. The latter are termed divergent dislocations.

Dislocation of the elbow requires considerable energy, and it is not surprising that a significant number of dislocations are associated with fractures of adjacent bony structures. A fracture-dislocation injury is referred to as a complex elbow dislocation. Immediate reduction of these dislocations is imperative to relieve pain and to prevent circulatory embarrassment or cartilaginous damage.

**Posterior Elbow Dislocation**

**Pathophysiology.** The mechanism of injury is a fall on the outstretched hand or wrist, the elbow being either extended or hyperextended at the time of impact. A valgus stress usually also occurs. The resultant forces lever the ulna from the trochlea and produce the dislocation.

**Clinical and Radiographic Features.** Patients hold the elbow in flexion at approximately 45 degrees and have marked prominence of the olecranon. Some elbow dislocations reduce before examination in the ED, presenting a confusing picture. In any case, significant diffuse tenderness and swelling are present. Neurovascular status must be checked because brachial artery and median nerve injuries have been described. Neurovascular injury may occur from numerous mechanisms, including the initial traction, local swelling, and entrapment during reduction. Repeat examinations are mandatory.

A radiographic example of elbow dislocation before reduction is provided in Figure 49-31. Radiographic evaluation is crucial before manipulation to rule out fractures that can mimic dislocation on examination. Also, several fractures commonly occur in conjunction with dislocation, and these need to be identified and treated when present. These include fractures of the distal humerus, radial head, and coronoid process.

**Management.** Orthopedic consultation is usually not necessary to proceed. Reduction should be attempted immediately especially if there is neurovascular compromise. Intra-articular injection of local anesthetic may provide adequate analgesia to allow for closed reduction. Procedural sedation is very helpful and often required to facilitate reduction. Rarely is a regional block or general anesthesia needed. Posterior dislocations are reduced with an assistant immobilizing the humerus and applying countertraction while traction is applied to the distal forearm. The ideal position is for the elbow to be flexed at 30 degrees with the forearm supinated while distal traction is applied. When the capitellum slides over the coronoid process, a coupling sound occurs as the articular surfaces mesh. If reduction is unsuccessful with this technique, the physician should apply downward pressure at the proximal forearm and apply pressure behind the olecranon while maintaining in-line traction. This downward force may help “unlock” the coronoid process, which may be trapped in the olecranon fossa. The joint is gently moved through its normal range of motion to check stability. If stable, the elbow is flexed to approximately 90 degrees and immobilized with a posterior plaster mold. The neurovascular status should be rechecked. Postreduction radiographs are important to avoid missing concomitant fractures of the coronoid process or radial head or, in children, separation of the medial epicondylar apophysis.

Postreduction management includes immobilization in a posterior splint with the elbow in as much flexion as circulation allows. The arm is suspended in a sling. Circular casting should be avoided initially. Patients can be discharged with instructions to apply ice, elevate, and watch for signs of vascular impairment. Patients should not be discharged until and unless they can follow such instructions. If the elbow is stable after reduction, gentle range-of-motion exercises may be initiated in 3 to 5 days. Unstable joints may require either prolonged immobilization in the presence of ligamentous instability or internal fixation for instability associated with fracture.

**Complications.** The most serious complication of elbow dislocation is vascular compromise. Severe disruption results in injury to the brachial artery in 8% of cases. Vascular injury should be sought when a wide opening between the tip of the olecranon and the distal humerus is palpated or seen on a radiograph. The presence of distal pulses is not proof of an intact artery, and if a question of vascular compromise
exists, emergent vascular studies or consultation is indicated. Median nerve traction injuries and entrapment also have been reported. Loss of median nerve function after reduction should prompt immediate orthopedic consultation. Recurrent dislocation of the elbow is rare.

**Medial and Lateral Dislocations**

Medial and lateral elbow dislocations are produced by a similar mechanism as in posterior dislocations with a vector of force displacing the ulna and radius as a unit either medially or laterally. The anteroposterior view is the key to determining these dislocations. Reduction is carried out with the arm in slight extension, but otherwise is similar to that for posterior dislocation. Care must be taken not to convert these to posterior dislocations during reduction. Complications and aftercare are the same as for posterior dislocations.

**Anterior Elbow Dislocation**

**Pathophysiology.** Anterior dislocations are rare and occur as a result of a blow from behind to the olecranon while the elbow is in the flexed position. Severe associated soft tissue trauma is present, including avulsion of the triceps mechanism or vascular disruption. These dislocations are frequently open.

**Clinical Features.** The upper arm appears shortened and the forearm elongated. The elbow is fully extended, and the forearm is supinated. The olecranon fossa is palpable posteriorly.

**Management.** Reduction of closed injuries is performed with distal traction of the wrist and a backward pressure on the forearm, while grasping the distal humerus. A click usually indicates that reduction has been achieved. These injuries have a higher incidence of vascular impairment than the more common posterior dislocation, but ulnar nerve injuries are unusual. Emergent orthopedic referral is advised and is mandatory for open injuries or when vascular disruption is suggested.

**Radial Head Subluxation**

**Pathophysiology**

Subluxation of the radial head is a common injury, representing more than 20% of upper extremity injuries in children. Children aged 1 to 4 years are most often affected, although cases have been reported in children 6 months to 15 years of age. Girls are affected more commonly than boys and the left arm is more commonly affected than the right. This injury is called *nursemaid’s elbow* or *pulled elbow* because it results from a sudden longitudinal pull on the forearm while the child’s arm is in pronation. Stretching of the annular ligament allows fibers to slip between the capitellum and the head of the radius, resulting in an inability of the child to supinate the arm. By the age of 5, the annular ligament becomes thick and strong and thus is far less likely to tear or be displaced. There is a recurrence rate of about 20% for this injury.

**Clinical and Radiographic Features**

The classic history, present approximately half of the time, is that of the forearm being pulled while in pronation with the elbow extended. Other mechanisms include direct trauma to the elbow or a twisting motion of the arm. Among children younger than 6 months, the mechanism of subluxation involves rolling over in bed, which may trap the involved forearm under the body with resulting longitudinal traction on the joint. Clinically the arm is held in passive pronation, with slight flexion at the elbow. The child is unable or unwilling to move the arm. Resistance to supination and tenderness on direct palpation over the head of the radius are present. Swelling, ecchymosis, and deformity are absent. Examination should include inspection and palpation of the entire extremity, including the clavicle.

Radiographs appear normal and are not required when the history suggests this injury. If there is swelling or deformity, if there is an uncharacteristic history, if the child does not resume use of the arm after reduction, or if there is a possibility of child abuse, appropriate radiographic studies are recommended. If palpation of the forearm, wrist, or humerus away from the elbow elicits reproducible tenderness, radiographs should be taken to exclude other diagnoses.

**Management**

Reduction may be attempted on children with typical presentations and is safe even when the classic history is absent. Supination-flexion method is the method most commonly used. Reduction is achieved by supination of the forearm while slight pressure on the radial head is applied with the examiner’s thumb. In one continuous motion, the elbow is supinated and flexed with gentle traction applied. A click often, but not always, is felt as the radial head reduces
Epicondylitis (Tennis Elbow)

Pathophysiology

Tennis elbow is a term first introduced in the 1880s to describe an inflammatory process that involves the radiohumeral joint or lateral epicondyle of the humerus. It is a common exercise-related syndrome, and the mechanism is thought to be repetitive pronation and supination of the forearm. The actual pathologic nature of this syndrome is unclear. Radiohumeral bursitis or synovitis, tendinitis of the common extensor tendon, periostitis of the lateral epicondyle, and entrapment by scar tissue of the radial nerve all have been suggested as culprits in this syndrome. Histologically the abnormality has been described as angiofibroblastic hyperplasia, a term subsequently modified to angiofibroblastic tendinosis.

The cause has been theorized to be a degenerative process because of the paucity of acute inflammatory cells seen histologically.54 Medial tennis elbow and posterior tennis elbow have been reported, the former involving the pronator teres and flexor carpi radialis insertions and the latter involving the triceps tendon. The following discussion pertains to lateral tennis elbow.

Clinical and Radiographic Features

Whatever the cause, the onset is usually gradual. Patients have complaints of dull pain over the lateral aspect of the elbow, increased by grasping or twisting motions. Tenderness is located over the lateral epicondyle or radiohumeral joint. Supination and pronation against resistance may be painful. Pain can be shown by stretching the wrist extensors. To test this, the elbow is extended, the forearm pronated, and the wrist fully dorsiflexed.

Radiographic findings may be normal, although with chronicity, calcifications may be present over the lateral epicondyle. Characteristic MRI findings also have been described, although MRI is not indicated and generally not available in the ED.55

Management

Traditional treatment includes protection, rest, ice, compression, elevation, and medication. Initial therapy includes avoidance of the inciting activity and immobilization with a sling. Nonsteroidal anti-inflammatory drugs are often used, but their efficacy probably is limited to their analgesic rather than their anti-inflammatory properties.56 Injection of a corticosteroid at the point of tenderness provides some pain relief in most patients.57-59 Because corticosteroids weaken collagen, premature resumption of heavy loading of the tendon at the lesion should be avoided, as should injection directly into the tendon.60 Patients with pain that persists despite treatment and a rehabilitation program should be referred for possible surgery.61 Modification of athletic technique is recommended after the symptoms subside.

Olecranon Bursitis

Pathophysiology

Although several bursae are located in the elbow region, the olecranon bursa is the one most often involved in an isolated pathologic process. Olecranon bursitis commonly is caused by repetitive minor trauma, such as leaning on the elbow during work activities. It also may result from an inflammatory process,
such as gout or an infectious process within the bursa (septic bursitis). Septic olecranon bursitis occurs most commonly in patients engaged in work that predisposes to repetitive trauma to the elbow, such as gardening or plumbing.

Clinical Features

Patients usually have progressive pain, tenderness, and swelling over the olecranon. Some patients with septic bursitis have an abrupt onset instead, with a rapid increase in pain over a few hours. On examination, the septic bursa is typically swollen, hot, erythematous, and tender. Flexion often is limited by pain brought on by tightening of the skin over the inflamed bursa. Minor breaks in the skin, frank abrasions, or healing lacerations over the bursa may be present. In one small series, 7 of 20 patients with septic olecranon bursitis were febrile (38.5–40.3°C), 75% had cellulitis, and 25% had regional adenopathy. Noninfectious bursitis usually presents with less warmth and erythema. The skin is intact, and swelling may be the only finding. The most important aspect of evaluation is the differentiation of a septic process from a benign inflammatory one. This differentiation may be difficult on clinical grounds because considerable overlap exists in the histories and physical findings.

Diagnostic Strategies

If doubt exists, aspiration of the bursa should be performed and the aspirate sent for crystals, white blood cell count, Gram's stain, and cultures. Unless it is frankly bloody, traumatic nonseptic olecranon bursitis usually has a leukocyte count of less than 1000 cells/mm³, whereas septic bursal fluid usually has greater than 10,000 white blood cells/mm³.

Management

Aspiration is diagnostic and therapeutic because relief of pressure relieves some of the pain. In cases of purulent bursitis, the bursa should be drained, and appropriate antibiotics should be begun in the ED. Pending culture results, empiric antibiotics should include coverage for routine skin organisms as well as methicillin-resistant *Staphylococcus aureus* (MRSA). Bursitis refractory to aspiration and appropriate antibiotics may require incision and drainage. Noninfectious bursitis can be managed with a compression dressing, ice, nonsteroidal anti-inflammatory medications, and avoidance of the inciting activity. Patients who have had their bursa aspirated should be rechecked within 24 to 48 hours to verify culture results and monitor their response to treatment.

Biceps Tendon Rupture

Pathophysiology

Biceps tendon rupture occurs most commonly in the proximal portion of the long head of the biceps. It is most common in middle-aged athletes or physical laborers who sustain repetitive microtrauma to the tendon. Patients experience a snapping sound and pain in the anterior shoulder during strenuous activities that produce rapid loading of the muscle. Rupture also occurs distally, usually as an avulsion from the insertion on the radial tuberosity, although ruptures at the musculotendinous junction occasionally occur. Rupture of the distal biceps tendon occurs almost exclusively in men, most commonly between the ages of 40 and 60, and most often involves the dominant arm.62 The inciting event is usually an unexpected extension force applied to the arm flexed at 90 degrees. The pathophysiology of tendon rupture is poorly understood, although tendon rupture generally occurs in the setting of underlying tendinosis. Diabetes, chronic renal failure, systemic lupus erythematosus, rheumatoid arthritis, and steroid or fluoroquinolone therapy all may result in tendinosis. Smoking has been shown to be strongly associated with distal biceps tendon rupture.63

Clinical Features

The diagnosis is usually obvious. In proximal tendon rupture, the patient usually has a visible defect at the top of the bicapital groove with bunching of the muscle distally. Flexion of the elbow produces pain at the proximal insertion. Flexion remains intact, however, because the short head of the biceps usually maintains its integrity. With distal ruptures, the patient complains of pain and tearing in the antecubital region. There is a visible deformity and palpable defect of the biceps muscle belly with weakness of elbow flexion and supination. If the tendon is completely ruptured, there is a bunching up of the muscle, and this effect is accentuated when the patient attempts flexion. Radiographs are not revealing and usually not necessary. MRI may be useful when a partial rupture is suggested.

Management

All patients require urgent referral to an orthopedist. Early anatomic repair of complete ruptures usually is recommended. Partial ruptures occasionally respond to conservative treatment, but also may require surgical repair. The arm should be splinted and the patient advised to apply ice and be given analgesics while awaiting orthopedic consultation.

**KEY CONCEPTS**

- Clinical decision rules for the elbow joint have not been validated. It is reasonable to obtain radiographs when there is significant limitation in range of motion, obvious deformity, joint effusion, or significant tenderness over any of the bony prominences or the radial head. In the absence of these, it would seem appropriate to omit radiographs in adults. The threshold for imaging should be lower in pediatric patients due to the presence of open growth plates and limitation in the physical exam.
- In children with wrist pain and traumatic mechanism of injury, the absence of a clear-cut explanation for the pain (e.g., no abnormal radiographic findings) should prompt consideration of an elbow injury causing referred pain to the wrist.
- In the setting of trauma, more than 90% of patients with the posterior fat pad sign of the elbow have intra-articular skeletal injury. In adults, a radial head fracture is implied, whereas in children, a supracondylar fracture is the probable underlying injury. In the absence of trauma, other causes of effusion (e.g., gout, infection, or bursitis) should be considered.
- The most common complication, radial nerve injury, occurs in 20% of humerus fractures. This is most often a benign neurapraxia that resolves spontaneously in most
patients, although recovery may take several months. Radial nerve injuries associated with penetrating trauma or open fractures are likely to be permanent and usually warrant operative exploration.

■ Generally the radius and ulna, bound together firmly by the annular ligament and interosseous membrane, displace as a unit and typically dislocate posteriorly, although anterior, medial, or lateral dislocations may occur.

■ Radiographic studies are not required when the history suggests radial head dislocation (nursemaid’s elbow). If there is swelling or deformity, if there is an uncharacteristic history, if the child does not resume use of the arm after reduction, or if there is a suggestion of child abuse, appropriate radiographic studies should be obtained.

■ Biceps tendon rupture occurs almost exclusively in men, most commonly between ages 40 to 60, most often involving the dominant arm, and usually subsequent to an unexpected extension force applied to the arm flexed at 90 degrees. Smoking, diabetes, chronic renal failure, systemic lupus erythematosus, rheumatoid arthritis, and steroid or fluoroquinolone therapy may predispose to this injury.

CHAPTER 50  Shoulder

Mohamud Daya and Yoko Nakamura

■ PERSPECTIVE

The shoulder joint is a unique and complex articulation unit. It has the largest range of motion of any appendicular joint in the body and can be moved through a space that exceeds a hemisphere in extent. The nature of such injuries has been long recognized: Wall paintings in Egyptian tombs from 3000 BCE show accurate drawings of manipulations (similar to the Kocher technique) used to reduce shoulder dislocations.1 Hippocrates may have been the first to outline extensively the diagnosis and treatment of shoulder dislocations.2

Shoulder injuries are commonly encountered in emergency medicine. Statistical studies show that 8 to 13% of all athletic injuries involve the shoulder and that shoulder dislocations account for more than 50% of all major joint dislocations seen in the emergency department (ED). Almost every major sport or athletic activity involves use of the shoulder joint in one way or another. The shoulder can be injured by trauma (indirect or direct) or by overuse. Traumatic injuries tend to occur in football and ice hockey, whereas overuse injuries (impingement syndromes) are more common in swimming and baseball. Shoulder injuries also are common in wrestling, tennis, volleyball, and javelin throwing.3

In general, children are vulnerable to the same injuries as those incurred by adults; however, the presence of the epiphysis and its growth plate changes the pattern of injuries.4 The strength of the joint capsule and its ligaments is two to five times greater than that of the epiphyseal plate. An injury that produces a sprain or dislocation in an adult often causes a fracture through the hypertrophic zone of the growth plate in a child. The shoulder girdle has epiphyseal plates at the acromion process, proximal humeral head, coracoid process, glenoid cavity, and medial end of the clavicle. Complete or greenstick fractures of the clavicle and fractures of the proximal humeral epiphysis are encountered more commonly in the pediatric population. Most shoulder injuries in children can be treated conservatively, with a good prognosis for full return of function.4

■ PRINCIPLES OF DISEASE

Anatomy

The shoulder girdle connects the upper extremity to the axial skeleton (Fig. 50-1). It consists of three bones, the clavicle, humerus, and scapula; three joints, the acromioclavicular, glenohumeral, and sternoclavicular joints; and one pseudoarticulation, the scapulathoracic.

The sternoclavicular joint (SCJ) represents the only true articulation between the upper extremity and the axial skeleton (Fig. 50-2). Stabilizers of this diarthrodial joint include the anterior and posterior sternoclavicular ligaments, the interclavicular ligament, and the costoclavicular ligament. The costoclavicular ligament opposes the pull of the sternocleidomastoid and is the most important stabilizing ligament.5 The SCJ participates in all movements of the upper extremity and is the most moved joint in the body.5 The superior mediastinum, with its great vessels, trachea, esophagus, thoracic duct, lung apices, and other important structures is immediately posterior to the joint.

The clavicle is an S-shaped bone that acts as a strut to support the upper extremity and keep it away from the chest wall. It articulates medially with the sternum and laterally with the acromion process. The clavicle provides the neck with an acceptable cosmetic appearance and protects the subclavian vessels and brachial plexus. Its middle third, which is thin and untethered, is the most commonly fractured segment.7

The acromioclavicular joint (ACJ) connects the lateral end of the clavicle with the medial aspect of the acromion process (Fig. 50-3). The diarthrodial acromioclavicular joint has little or no bony stability and is dependent on the associated ligaments and muscles for support.8 The weak acromioclavicular ligaments provide posterior support while the clavicular and acromial attachments of the deltoid and trapezius muscles provide static and dynamic support for the superior aspect of the joint. The most important stabilizers are the coracoclavicular ligaments (conoid and trapezoid), which provide vertical and anterior support.

The scapula is a flat triangular bone that forms the posterior aspect of the shoulder girdle. The thin body of the scapula lies flat against the posterior thorax and widens laterally to form the glenoid fossa. Its thickened borders are the attachment sites for 18 muscle origins and insertions.7 Its thick muscle coat and ability to recoil along the posterior chest wall protect the scapula from both direct and indirect trauma.

A synovial membrane extends from the glenoid fossa to the humeral head. The membrane is large and redundant inferiorly to accommodate the extensive range of movement. Overlying the synovial membrane is a loose and redundant fibrous capsule. Anteriorly, the capsule is thickened to form the superior, middle, and inferior glenohumeral ligaments. The ante-
The glenohumeral articulation is a ball-and-socket–type joint that depends largely on associated capsule, muscles, and ligaments for stability (Fig. 50-4). A negative intracapsular pressure completes the stabilization mechanism. The absence of bony stability permits a range of motion, however, that is greater than that of any other joint in the body.

The proximal humerus articulates with the glenoid fossa and provides for the attachment of many important muscles. The supraspinatus, infraspinatus, and teres minor insert onto facets of the greater tuberosity, whereas the subscapularis inserts onto the lesser tuberosity. Together, this group of muscles forms the rotator cuff, which helps stabilize the humeral head within the glenohumeral joint (Fig. 50-5). The long head of the biceps tendon originates from the supraglenoid tubercle and ascends over the humeral head to enter the arm via the bicipital groove. The long head acts as an additional stabilizer for the superior and anterior aspects of the glenohumeral joint. The pectoralis major, latissimus dorsi, and teres major muscles all insert into the humeral intertubercular groove. Displacements encountered with fractures of the humerus usually reflect the pull of these attached muscle groups. The proximal humerus is composed primarily of trabecular bone with a thin cortical shell. Changes in bone density with age (osteoarthritis) greatly increase the risk of fractures in this area.

The brachial plexus and subclavian vessels enter the shoulder girdle complex superiorly between the clavicle and the first rib, traverse under the coracoid process, and exit anterior to the inferior aspect of the glenohumeral joint as the median, ulnar, and radial nerves and axillary vessels. These nerves represent the final branches of the upper brachial plexus (nerve roots C5 to C8), and injuries to the brachial plexus invariably result in significant shoulder dysfunction.

## History

Most complaints usually involve some combination of pain, stiffness, instability, and weakness. Pain can result from many different conditions extrinsic and intrinsic to the shoulder. Extrinsic sources of shoulder pain include disorders of the cervical spine, thoracic outlet syndromes, and Pancoast tumors. In addition, pain can be referred to the shoulder from myocardial processes, diaphragmatic irritation (e.g., subphrenic abscess, lower lobe pneumonia, splenic hematoma, ruptured ectopic pregnancy, gallbladder disease), and gastric or pancreatic diseases.

Acute intrinsic pain usually is associated with a traumatic event. The most important factors to determine are the time and mechanism of injury, its precise location, and the intensity of the pain. Occasionally the patient may have acute pain in the absence of associated trauma (e.g., calcific tendinitis). Shoulder pain also can manifest in an insidious manner, unrelated to any precipitating factor. In these instances, the duration, location, character, and aggravating and alleviating factors of the pain should be noted. Intrinsic shoulder pain in general does not radiate past the elbow.

Stiffness usually signifies a restricted range of motion resulting from an underlying painful condition of the shoulder. Instability can be seen in the form of an obvious subluxation or dislocation. Alternatively, the patient may describe the sensation of the shoulder's almost “going out.” A rotator cuff tear...
or an underlying nerve lesion usually causes significant shoulder weakness.

Physical Examination

The shoulder should be inspected from the anterior, posterior, and lateral positions. Any obvious deformity, ecchymosis, lac-
process, humeral head, and glenoid rim. Some degree of abduction is required to obtain the axillary view. The difficulty in obtaining this view has led to the popularity of the trans­scapular view (see Fig. 50-7B). Advantages of this projection include its simplicity and reproducibility and a clear delineation of anatomic structures. In this view, the scapula is projected as a Y, with the body forming the lower limb and the coracoid and acromion processes forming the upper limbs. The humeral head normally is superimposed over the glenoid, which is located at the junction of the three limbs. This view is particularly useful in identifying anterior and posterior geln­ohumeral dislocations. The apical oblique view (obtained by placing the injured shoulder in a 45-degree oblique position and angling the central ray 45 degrees caudally) shows the glenohumeral joint in a unique coronal projection. This view can be obtained easily and painlessly and has been found to be more sensitive than the trans­scapular view for detecting bone and joint abnormalities in the injured shoulder.

Plain radiographs are the mainstay of the radiologic examination in the ED, but in selected circumstances, additional bone and soft tissue details may be obtained using computed tomography (CT) or magnetic resonance imaging (MRI).13

■ SPECIFIC INJURIES

Fractures

Clavicle

Pathophysiology. The clavicle accounts for 5% of all fractures and is the most commonly fractured bone in children. Epidemiologic studies in adults have documented an annual incidence rate of 30 to 50 per 100,000 population, with a 2:1 male-to-female ratio.14,15 Clavicular fractures are classified anatomically and mechanistically into three groups. Fractures of the medial third are uncommon (5%) and occur as a result of a direct blow to the anterior chest. Fractures of the middle third are the most frequent (Fig. 50-8), accounting for 80% of all injuries. The usual mechanism of injury involves a direct force applied to the lateral aspect of the shoulder as a result of a fall, sporting...
Figure 50-7. Normal axillary (A), true anteroposterior (B), and transscapular lateral (C) radiographic views (i.e., trauma series) of the shoulder.

Figure 50-8. Displaced midclavicular fracture.

injury, or motor vehicle accident. Fractures of the lateral third (15%) result from a direct blow to the top of the shoulder and are classified further into three subtypes. Type I fractures are stable and minimally displaced because the coracoclavicular ligament remains intact. Type II fractures are associated with a torn coracoclavicular ligament and have a tendency to displace because the proximal fragment lacks any stabilizing forces. Type III injuries involve the articular surface (Fig. 50-9).

Clinical Features. The patient has pain over the fracture site, and the affected extremity is held close to the body. With fractures of the middle third, the shoulder typically is slumped downward, forward, and inward. This positioning is a result of the effect of gravity and the pull of the pectoralis major and latissimus dorsi on the distal fragment. The proximal fragment often is displaced upward by the action of the sternocleidomastoid. The head is often tilted toward the injured side in an attempt to relax the effects of these displacing muscular forces. Ecchymosis, crepitus, and a palpable or visible deformity may be noted over the fracture site. Although associated neurovascular injury is rare, the close proximity of the subclavian vessels and brachial plexus demands a thorough assessment. Associated pneumothorax and pulmonary injuries are also rare unless an open fracture is present. The newborn clavicle fracture suffered during childbirth classically manifests as an uneventful “lump,” representing the area of subsequent callus formation, in a child brought in by a concerned parent.

Management. Principles of initial management include pain control, immobilization, and proper follow-up care. Fractures
of the clavicle can be immobilized with supportive devices, such as a simple sling or sling and swathe (Fig. 50-10). Another immobilization technique for midclavicular fractures still recommended in the orthopedic literature, although its efficacy is not supported by evidence, is the clavicular (figure-of-eight) splint (Fig. 50-11). This splint is applied after closed reduction of the fracture, which is accomplished by pulling the shoulders up and back. Such reductions are difficult to maintain and may be associated with increased discomfort at the fracture site. Use of clavicular splints also can lead to skin irritation and compression of the neurovascular bundle in the axilla. Because some degrees of malunion and shortening are associated with an acceptable functional and cosmetic outcome, treatment with a simple sling is a valid and appropriate alternative to the clavicular splint in the ED.18

Disposition. Immediate orthopedic consultation should be sought for open fractures or fractures associated with neurovascular injuries or skin tenting. More urgent orthopedic consultation (before 72 hours) is recommended for type II lateral clavicle fractures because these fractures have a 30% incidence of nonunion and may require surgical repair.16 Severely comminuted or displaced fractures of the middle third (defined as more than 20 mm of initial shortening) may also benefit from early orthopedic referral because these injuries have been associated with a higher incidence of nonunion.19,20 Greenstick fractures of the midclavicle are common in children (Fig. 50-12). Most of these fractures are nondisplaced and heal uneventfully. Initial radiographs may appear normal despite suggestive clinical findings. In these instances, the arm should be immobilized in a simple sling and the radiographic evaluation repeated in 7 to 10 days if symptoms persist. Most fractures of the clavicle heal uneventfully, and follow-up can be provided by a primary care physician. A sling should be worn until repeat radiographs show callus formation and healing across the fracture site. Passive shoulder range-of-motion exercises (Fig. 50-13) are encouraged to reduce the risk of adhesive capsulitis. Younger children generally require shorter periods of immobilization (2 to 4 weeks) than adolescents and adults (4 to 8 weeks). Vigorous competitive play should be avoided until the bone healing is solid. A full motion of the shoulder and an absence of pain are two good clinical signs that the fracture has healed.

Complications. Complications are unusual, with the most common ones being delayed union or nonunion.14-16 Complications after fractures of the medial third resemble those associated with posterior sternoclavicular dislocations. Fractures of the middle third have been associated with injuries to the neurovascular bundle and the pleural dome. Articular surface injuries (type III lateral clavicle fractures) can lead to subsequent osteoarthritis of the ACJ.
An uncommon but important association is that between clavicle fractures and atlantoaxial rotatory displacement (AARD). Most cases occur in girls younger than 10 years of age. The pathophysiology may involve a lax or disrupted alar ligament along with sternocleidomastoid spasm. Early diagnosis is important because delayed diagnosis can lead to a chronic deformity requiring surgery. AARD should be suspected if the child has a clavicle fracture and demonstrates a “cocked-robin” position with the head bent toward the fractured side but rotated in the opposite direction. The injury is best demonstrated by CT and, if recognized early, can be treated with a soft cervical collar or halo traction.

Scapula

Pathophysiology. Fractures of the scapula are rare injuries, with an annual incidence of 10 to 12 per 100,000 population. They account for 1% of all fractures and occur primarily in men 30 to 40 years old. In general, considerable force and energy are required to fracture the scapula. Most fractures result from high-speed motor vehicle collisions (MVCs), falls from heights, or crush injuries. Coracoid process fractures usually are avulsive, and glenoid rim fractures are commonly associated with anterior glenohumeral dislocations. An acromial process fracture usually results from a direct blow to the top of the shoulder.

The most important aspect of scapular fractures is the high incidence (75% to 98%) of associated injuries to the ipsilateral lung, chest wall, and shoulder girdle complex. The most common associated orthopedic injuries are fractures of the ribs, proximal humerus, and clavicle. Associated lung injuries include pneumothorax, hemothorax, and pulmonary contusion; these may manifest in delayed fashion, 2 to 3 days after the initial injury. Associated injuries of the head, spinal cord, brachial plexus, and subclavian or axillary vessels are more significant but less common. Of note, blunt aortic injury is not more common in patients with a fractured scapula.

Fractures of the scapula can be classified according to their anatomic location. In the system proposed by Ada and Miller, type I fractures involve the acromion process, scapular spine, or coracoid process. Type II fractures involve the scapular neck (Fig. 50-14), and type III injuries are intra-articular fractures of the glenoid fossa. The most common are type IV fractures, which involve the body of the scapula.

Clinical Features. In a conscious patient, the shoulder is adducted, and the arm is held close to the body. Any attempts at movement result in significant pain. Associated tenderness, crepitus, or hematoma may be noted over the fracture site. The clinical findings occasionally mimic those with a rotator cuff tear. Hemorrhage into the rotator cuff associated with the
scapula fracture can result in spasm and a temporary reflex inhibition of function (pseudorupture).\textsuperscript{23} The presence of a scapula fracture mandates a thorough search for associated thoracic, intracranial, orthopedic, and neurovascular injuries.

**Diagnostic Strategies: Radiology.** The trauma series of shoulder radiographs will reveal most fractures, as will careful examination of the scapula on the trauma chest radiograph. The axillary lateral view is especially useful in evaluating fractures of the glenoid fossa and the acromion or coracoid process.\textsuperscript{9} An os acromiale (unfused acromial process epiphysis) is present in 3% of the population and should not be confused with a fracture of the acromion.\textsuperscript{9} A comparison film can be useful because the abnormality is present bilaterally in 60% of cases. In many patients, fractures of the scapula initially are overlooked despite being readily apparent on the initial supine trauma chest radiograph because of the life-threatening nature of the associated injuries.\textsuperscript{9}

**Management.** Most fractures, including fractures with severe comminution and displacement, heal rapidly with conservative therapy.\textsuperscript{6,23} Initial therapy consists of analgesia and immobilization in a sling to support the ipsilateral upper extremity. Passive shoulder exercises (see Figure 50-13) are initiated as soon as discomfort subsides, to reduce the risk of adhesive capsulitis. In general, patients require a sling for 2 to 4 weeks.

Fractures of the body and spine usually require no further therapy. Nondisplaced fractures of the acromion process also respond well to conservative therapy. Displaced acromial fractures that impinge on the glenohumeral joint require surgical management. Rarely, the acromion is fractured as part of a superior dislocation of the humeral head. In these instances, an accompanying tear of the rotator cuff is invariably present and requires surgical repair. If the coracoclavicular ligaments remain intact, fractures of the coracoid process respond well to conservative therapy. Severely displaced coracoid fractures with ruptured coracoclavicular ligaments usually require open reduction and internal fixation.\textsuperscript{6} Scapular neck and glenoid fossa fractures present the most difficult management issues. Although most of these injuries do well with conservative therapy, open reduction and internal fixation are recommended for severely displaced or angulated fractures.\textsuperscript{23}

In a review of 520 scapula fractures from 22 case series, Zlowodzki and coworkers reported that 80% of all fractures with glenoid involvement were treated operatively, whereas 83% of all neck injuries and 99% of all isolated scapula body fractures were treated nonoperatively.\textsuperscript{22}

**Complications.** Associated injuries of the ipsilateral lung, chest wall, and shoulder girdle account for most complications after fractures of the scapula. A shear-type brachial plexus injury has been associated with fractures of the acromion process. Neurovascular (brachial plexus, axillary artery) injuries also have been reported with fractures of the coracoid process.\textsuperscript{6} Scapular neck, body, or spine fractures that extend into the suprascapular notch can injure the suprascapular nerve.\textsuperscript{6} Delayed complications include adhesive capsulitis and rotator cuff dysfunction.

**Proximal Humerus**

**Pathophysiology.** Fractures of the proximal humerus are common and account for 4 to 5% of all fractures.\textsuperscript{23} A prospective Swedish study reported an incidence of 114 per 100,000 population, with a mean age at occurrence of 67 years and a female-to-male ratio of 3:1.\textsuperscript{25} These fractures occur primarily in the older population, in whom structural changes associated with aging (osteoporosis) weaken the proximal humerus, predisposing it to injury. Although most of these injuries involve minimal displacement and are adequately managed with conservative therapy, significantly displaced fractures may require operative intervention. Displacements encountered with fractures of the humerus usually reflect the pull of the attached muscle group.

Fractures of the proximal humerus separate along old epiphyseal lines, producing four distinct segments consisting of the articular surface (anatomic neck), greater tuberosity, lesser tuberosity, and humeral shaft (surgical neck). The Neer classification system (Fig. 50-15) is based on the relationship of these fracture fragments.\textsuperscript{27,28} In this system, a segment is considered displaced if it is angled greater than 45 degrees or separated more than 1 cm from the neighboring segment. Because this classification system considers only displacement, the number of fracture lines is irrelevant. There are four major categories of fracture: minimal displacement (Fig. 50-16), two-part displacement (Fig. 50-17), three-part displacement, and four-part displacement. When present, anterior and posterior dislocations are included as part of the classification. Impaction and head-splitting fractures are classified separately.

The classic mechanism of injury involves a fall on an outstretched abducted arm. Concurrent pronation limits further abduction and lever the humerus against the acromial process; this produces a fracture or dislocation, depending on the tensile strengths of the bone and surrounding ligaments. Older patients are prone to fracture, whereas younger persons are apt to have dislocations. The combined injury (fracture and dislocation) may be seen in middle-aged patients. Proximal humerus fractures also may result from a direct blow to the lateral side of the arm or from an axial load transmitted through the elbow. High-energy mechanisms and polytrauma are more common in younger persons.

**Clinical Features.** The affected arm is held close to the body, and movement is restricted by pain. Tenderness, hematoma,
ecchymosis, deformity, or crepitus may be noted over the fracture site. A thorough neurovascular examination is essential to identify associated injuries of the axillary nerve, brachial plexus, or axillary artery. The three-view trauma series of shoulder radiographs will allow for assessment of the number of fracture fragments and degree of displacement or angulation.

**Management.** Minimally displaced fractures (see Fig. 50-16) constitute 80 to 85% of all cases. No displacement or angulation is present, and the fracture segments are held together by the capsule, periosteum, and surrounding muscles. Initial treatment consists of adequate analgesia and immobilization with a sling or sling and swathe device. The former is more comfortable, and a Cochrane review of 12 randomized trials found only limited evidence that use of special bandage immobilization affected time to fracture union or functional outcome.\(^2^9\) Traditionally, it has been recommended that immobilization be continued until clinical union is achieved (head and shaft are seen to move together). The Cochrane review also noted that immediate or earlier commencement of physiotherapy (within 1 week) resulted in less pain and faster recovery than with prolonged immobilization.\(^2^9\) Initial passive exercises (see Fig. 50-13) are gradually replaced by more active and resistive exercises. Most nondisplaced fractures heal over 4 to 6 weeks.

The treatment of two-part, three-part, and four-part displaced fractures is beyond the scope of this discussion. An orthopedic surgeon should be consulted, because many of these injuries require operative repair.\(^2^8\) Prospective and retrospective observational studies, however, have failed to show a significant functional difference between operative and nonoperative treatment of displaced two-part and three-part fractures in elderly patients. Current literature continues to support operative treatment of four-part fractures in the elderly when the procedure of choice is hemiarthroplasty.\(^3^0\)

Fracture-dislocation injuries also may require treatment by an orthopedic surgeon. Of note, reductions of these injuries in the ED often are unsuccessful, and these manipulations can cause separation of previously undisplaced segments. Closed reduction under radiologic control and general anesthesia may be preferable.\(^2^9\)

Posterior glenohumeral dislocations usually are associated with anteromedial impression fractures of the articular surface. A similar fracture of the posterolateral aspect of the humeral head is present with anterior dislocations (Hill-Sachs deformity). Impression fractures involving less than 20% of the articular surface usually are stable. With more than 20% involvement, the reduction usually is unstable and requires surgical repair.

**Complications.** The most common complication of proximal humeral fractures is adhesive capsulitis (so-called frozen or stiff shoulder). This complication can be prevented by the early initiation of pendular shoulder exercise, along with a thorough rehabilitation program. One of the most devastating complications is that of avascular necrosis (AVN) of the humeral head. The highest rate of AVN (up to 90%) has been documented for four-part fractures.\(^3^0\) Repeated forceful attempts at reduction of fracture-dislocations may be associated with subsequent heterotopic bone formation (myositis ossificans). Neurovascular injuries (axillary nerve, brachial plexus, and axillary artery) may be encountered with displaced surgical neck fractures and fracture-dislocations.

**Proximal Humeral Epiphysis**

**Pathophysiology.** Fractures of the proximal humeral epiphysis are uncommon and account for 10% of all shoulder fractures in
The injury can occur at any age while the epiphysis remains open but is most common in boys 11 to 17 years of age. The most common mechanism of injury involves a fall onto the outstretched hand, and the fracture typically occurs through the zone of hypertrophy in the epiphyseal plate. Injuries can be classified according to their location (Salter system), stability, and degree of displacement.

**Clinical Features.** The patient holds the injured arm tightly against the body by the opposite hand. The area over the proximal humerus is swollen and extremely tender to palpation. Radiographs obtained at 90 degrees to each other confirm the diagnosis. Comparison views may be helpful with minimally displaced fractures.

**Management.** Fractures of the proximal humeral epiphysis should not be taken lightly, because the potential for growth disturbance exists even under the most ideal conditions. The active healing process at the site of an epiphyseal injury makes delayed reduction extremely difficult. Early orthopedic consultation should be obtained for all such injuries. Children younger than 6 years of age usually have Salter I epiphyseal injuries (Fig. 50-18), which can be treated conservatively with sling and swathe immobilization and analgesic agents. Children older than 6 years usually have a Salter II epiphyseal injury. Salter II injuries with more than 20 degrees of angulation should be reduced. Closed reduction is accomplished by reversing the mechanism of injury. Imperfect reductions often are acceptable because growth and remodeling correct the deformity with time. After reduction, unstable injuries should be immobilized in a shoulder spica cast, whereas stable lesions can be immobilized with a sling and swathe. Fractures of the proximal humeral epiphyses generally heal in 3 to 5 weeks.22

**Complications.** Complications are rare and include malunion, growth plate disturbances, and injuries to the neurovascular bundle. Markedly displaced or angulated fractures are more likely to result in a residual loss of mobility.31

**Dislocations**

**Sternoclavicular.** Sternoclavicular joint (SCJ) dislocations are infrequent and account for less than 1% of all dislocations.33 Significant forces are required to disrupt the strong ligamentous stabilizers of this joint. The most common causes are MVCs and injuries sustained in contact sports, such as rugby or football. The SCJ can dislocate in an anterior or a posterior direction. Anterior dislocations, which result from indirect forces, are more common (9:1 ratio).3 The usual mechanism of injury (Fig. 50-19) involves an anterolateral force to the shoulder, followed by backward rolling, which lever the medial clavicle out of its articulation. Posterior dislocations (Fig. 50-20) can result from a direct blow to the medial clavicle (30%) or from delivery of a posterolateral force to the shoulder, followed by inward rolling (70%). Posterior dislocations can be associated with life-threatening injuries within the superior mediastinum.

Injuries to the SCJ can be graded into three types. A grade I injury is a mild sprain secondary to stretching of the sternoclavicular and costoclavicular ligaments. A grade II injury is associated with subluxation of the joint (anterior or posterior) secondary to rupture of the sternoclavicular ligament. The costoclavicular ligament remains intact. Complete rupture of the sternoclavicular and costoclavicular ligaments results in a grade III injury (dislocation). In patients younger than 25 years of age, these actually represent Salter type I injuries, because the medial epiphysis of the clavicle has not yet fused.34

**Clinical Features.** Clinical suspicion is the most important factor in diagnosing these injuries, and prompt diagnosis is vital because it is associated with a better prognosis. Patients will present with the injured extremity flexed at the elbow and supported across the trunk by the opposite arm. Pain results from any movement of the upper extremity or lateral compression of the shoulders. The SCJ may be mildly swollen and tender to palpation. With an anterior dislocation, the displaced medial end of the clavicle may be palpable. Posterior dislocations are associated with more severe pain, and the neck is often flexed toward the injured side.5 The clavicular notch of the sternum may be palpable, and complaints of hoarseness, dysphagia, dyspnea, and weakness or paresthesias in the upper extremities have been documented. Rarely, airway complications can occur. These patients should be examined thoroughly to identify any injuries to superior

**Figure 50-18.** A, Salter I injury of the right proximal humeral epiphysis. B, Normal left side is included for comparison.

**Figure 50-19.** Mechanisms that produce anterior and posterior displacements of the sternoclavicular joint. A, When the patient is lying on the ground and a compression force (upper arrow) is applied to the posterolateral aspect of the shoulder, the medial end of the clavicle is displaced posteriorly (lower arrow). B, When the lateral compression force (upper arrow) is directed from the anterior position, the medial end of the clavicle is displaced anteriorly (lower arrow). The same mechanism could apply with any type of lateral compression injury of the shoulder. (From Neer CS, Rockwood CA: Fractures and dislocations of the shoulder. In Rockwood CA, Green DP [eds]: Fractures in Adults, 4th ed. Philadelphia, JB Lippincott, 1984.)
mediastinal or intrathoracic structures. The presence of cyanosis and venous congestion of the neck and arm is typical of an innominate vein injury.\(^\text{30}\) When necessary, appropriate consultation should be obtained immediately.

**Diagnostic Strategies: Radiology.** Although the diagnosis of sternoclavicular dislocation can be made clinically, it should be confirmed radiologically. Findings on standard anteroposterior, oblique, and specialized (40-degree cephalic tilt) views often are difficult to interpret because of overlapping rib, sternum, and vertebral shadows. These dislocations and associated injuries are best visualized by CT (see Fig. 50-20).\(^\text{13}\) Ultrasound imaging also may be a useful adjunct in some circumstances.\(^\text{5}\)

**Management.** Treatment of grade I injuries includes immobilization (simple sling), adequate analgesia, and primary care follow-up. Immobilization generally is maintained (1 to 2 weeks) until full painless motion is restored. Grade II injuries should be immobilized with a sling or soft clavicular (figure-of-eight) splint and referred for orthopedic follow-up care. The figure-of-eight splint is preferred because it maintains the clavicle in a more anatomic position. Grade II injuries require a longer course of immobilization (3 to 6 weeks) and are more likely to be associated with persistent pain.\(^\text{5,6}\) All grade III injuries should be managed by closed reduction.

Anterior dislocations may be reduced in the ED after orthopedic consultation and intravenous analgesia (Fig. 50-21). A rolled sheet is placed posteriorly between the shoulder blades to elevate both shoulders approximately 5 cm above the table. Traction is applied to the arm in an extended (10- to 15-degree) and abducted (90-degree) position. If reduction does not occur, an assistant can add inward pressure on the medial end of the clavicle. Stable reductions should be maintained in a clavicular splint and referred for orthopedic follow-up care.\(^\text{5,6}\) Most reductions are unstable. Because the deformity is primarily cosmetic and not functional, the current treatment of choice for recurrent anterior dislocations is benign neglect.

Posterior dislocations constitute true orthopedic emergencies and should be reduced expeditiously.\(^\text{5}\) Ideally, reduction of posterior dislocations should be attempted in the operating room with the patient under general anesthesia, although it can be attempted in the ED with use of conscious sedation. Emergency reduction may be required for patients with airway obstruction or vascular compromise. The patient is positioned as described previously, and traction is applied in an extended and abducted position. If traction alone does not reduce the dislocation, concurrent clavicular manipulation may be helpful. After sterile preparation of the skin, the clavicle shaft is grasped with a sterile towel clip and pulled out anterolaterally. When reduced, these injuries generally are stable and can be immobilized with a clavicular splint. Buckerfield and Castle\(^\text{36}\) described an alternate method of reduction for posterior dislocations. In this technique, traction is applied to the adducted arm while both shoulders simultaneously are forced posteriorly using direct pressure. This technique levered the clavicle into place and requires much less force than the traditional abduction-extension method.

**Complications.** Complications of anterior injuries are primarily cosmetic. By contrast, 25% of posterior dislocations may be complicated by life-threatening injuries to intrathoracic and superior mediastinal structures. Ono and colleagues reviewed data for 102 cases reported in the literature as of 1998 and documented complications in 31 patients (30%), with three deaths.\(^\text{35}\) These include compression or laceration of the great vessels, tracheoesophageal fistula, tracheal compression, pneumothorax, thoracic outlet syndrome, and brachial plexus injuries. A potential long-term complication of both anterior and posterior injuries is degenerative osteoarthritis.

**Acromioclavicular Joint**

**Pathophysiology.** Injuries of the ACJ occur primarily in young men and account for 25% of all dislocations about the shoulder girdle.\(^\text{50}\) The annual incidence is 15 per 100,000 population, and most injuries result from participation in contact sports,
PART II

• Orthopedic Lesions

Rockwood. Type I injuries are sprains of the acromioclavicular joint, with no separation of the clavicle and acromion. There are minor tears in the acromioclavicular ligaments, and muscle disruptions are similar to the disruptions encountered in type II injuries, but the clavicle is displaced either posteriorly into the trapezius (type IV) or superiorly in an exaggerated (coracoclavicular distance increased 100 to 300%) fashion (type V). In the rare type VI injury, the clavicle is displaced inferiorly.

Clinical Features. Patients should be examined while they are in the sitting or standing position because the supine position can mask ACJ instability. It is helpful to visualize both shoulders simultaneously to assess for symmetry. Type I and type II injuries are associated with mild tenderness and swelling over the ACJ margin, with minimal deformity. A full range of motion often is possible, although painful. Patients with type III, IV, V, and VI injuries usually have severe pain and hold the arm tightly adducted to reduce traction stress across the joint. In type III injuries, the shoulder hangs downward and the clavicle rides high, producing a characteristic clinical deformity. In type IV injuries, the clavicle may be palpable posteriorly, and in type V injuries, the clavicle may be palpable subcutaneously above the acromion. In type VI injuries, the shoulder assumes a flattened clinical appearance as seen from the side.

Diagnostic Strategies: Radiology. The energy settings used for the three-view shoulder trauma series usually overpenetrate the ACJ. Specific ACJ views that use one-third to two-thirds less intensity should be ordered. The recommended projections include an anteroposterior view of both joints on a single wide film, an axillary lateral view, and a 15-degree cephalic tilt view. The axillary lateral view is useful for identifying associated fractures and posterior dislocation of the clavicle. The normal coracoclavicular distance ranges between 11 and 13 mm. A difference of more than 5 mm between the injured and uninjured sides is diagnostic of a complete coracoclavicular disruption. With type I injuries, the radiographic appearance is essentially normal. With type II injuries, radiographs show widening of the joint and a slight upward or posterior displacement of the clavicle but a normal coracoclavicular distance. With type III, IV, and V injuries, radiographic features include a widened joint, an increased coracoclavicular distance, and either superior or posterior displacement of the clavicle (Fig. 50-23). Historically, stress views of the ACJ have been recommended to differentiate between type II and type III injuries. Such views lack efficacy for this purpose, and their routine use is unnecessary.

Management. Type I and II injuries should be immobilized in a sling for comfort and to protect against further injury. Patients with these injuries should be referred for follow-up with their primary care physician. When pain has subsided (1 to 3 weeks), range-of-motion and strengthening exercises can begin, with a return to sports when pain-free function has been achieved.

Type IV, V, and VI injuries require early surgical treatment. The management of type III injuries has changed dramatically since the 1980s. Most studies have concluded that conservative treatment provides functional results equivalent to or, in some cases, better than those obtained with surgical intervention. In addition, surgical patients have longer recovery times and higher complication rates. The main complications of conservative therapy are the persistence of nuisance symp-
Anterior dislocations are rare. They account for most of the remainder, whereas inferior and superior dislocations account for 95 to 100,000, and two distinct age peaks are recognized, the first in men 20 to 30 years of age and the second in older women. Anterior dislocations account for 95 to 97% of all glenohumeral dislocations. Posterior dislocations are extremely rare and involve the addition of strong lateral to medial forces that push the humeral head medially.

Complications. The most common concurrent injuries are associated fractures of the clavicle and coracoid process. The most common complications of ACJ injuries are residual symptomatic instability and tenderness over the joint due to secondary degenerative changes. Acromioclavicular arthritis typically manifests as an impingement syndrome with shoulder pain between 120 and 180 degrees of abduction.

Glenohumeral Dislocations

Perspective. The glenohumeral joint is the most commonly dislocated major joint in the body. The lack of intrinsic bone stability in conjunction with its wide range of motion predisposes the joint to dislocations. The annual incidence is 17 per 100,000, and two distinct age peaks are recognized, the first in men 20 to 30 years of age and the second in older women. The glenohumeral joint can dislocate anteriorly, posteriorly, inferiorly, or superiorly. Anterior dislocations account for 95 to 97% of all glenohumeral dislocations. Posterior dislocations account for most of the remainder, whereas inferior and superior dislocations are rare.

Anterior Dislocations

Pathophysiology. Anterior dislocations can result from indirect or direct forces. The most common mechanism of injury consists of an indirect force transferred to the anterior capsule from a combination of abduction, extension, and external rotation. In younger persons, the injury usually is sustained during athletic activities involving rapid movements, and a characteristic pathologic feature is avulsion of the anteroinferior glenohumeral ligament with capsulolabral detachment (Bankart lesion). In older patients, a fall onto the outstretched arm is the more common mechanism of injury, and an accompanying rotator cuff tear is common. Rarely, a direct force applied to the posterolateral aspect of the shoulder can force the humeral head out of the glenoid fossa anteriorly.

Anterior dislocations can be classified according to their etiology (traumatic or nontraumatic), frequency (primary or recurrent), and the anatomic position of the dislocated humeral head. After dislocation, the humeral head can assume a subcoracoid, subglenoid, subclavicular, or intrathoracic position (Fig. 50-24). The subcoracoid is the most common type of anterior dislocation. The head is displaced anteriorly and rests on the scapular neck inferior to the coracoid process. The next most common type is the subglenoid dislocation, in which the head is anterior and inferior to the glenoid fossa. Together, the subcoracoid and subglenoid types account for 99% of all anterior dislocations. Subclavicular and intrathoracic dislocations are extremely rare and involve the addition of strong lateral to medial forces that push the humeral head medially.

Clinical Features. The patient is in severe pain, with the dislocated arm held in slight abduction and external rotation by the opposite extremity. The lateral edge of the acromion process is prominent, and the normally rounded shoulder assumes a “squared-off” appearance. The coracoid process is indistinct, and the anterior shoulder appears full. The patient leans away from the injured side and cannot adduct or internally rotate the shoulder even slightly without severe pain. A neurovascular examination is performed to identify associated injuries of the brachial plexus, axillary nerve, radial nerve, or axillary artery. The reported incidence of axillary nerve injuries after anterior glenohumeral dislocation ranges from 5 to 54%, and they are more frequent in patients older than 50 years of age. Axillary nerve function can be assessed by testing for sensation over the lateral aspect of the shoulder and by testing motor function of the teres minor and deltoid muscles. Deltoid function is tested by having the patient attempt shoulder abduction while the examiner feels for muscle contraction. Motor testing is more accurate because sensory testing can be misleading owing to the presence of overlapping cutaneous nerve root dermatomes.

Diagnostic Strategies: Radiology. The trauma series of radiographs will confirm the clinical diagnosis and identify the position of the humeral head (Fig. 50-25). Associated fractures may be present in 50% of cases. The most common of these is a compression fracture of the posterolateral aspect of the humeral head caused by forceful impingement against the anterior rim.
of the glenoid fossa. This defect in the humeral head, or Hill-Sachs deformity (see Fig. 50-25), is reported to be present in 11 to 50% of all anterior dislocations. The actual incidence is probably much higher, because minor compression fractures are difficult to visualize on plain radiographs. The defect is best visualized on an internal rotation anteroposterior view of the glenohumeral joint. A corresponding fracture of the anterior glenoid rim (Bankart’s fracture) is present in approximately 5% of cases.42 Avulsion fractures of the greater tuberosity are present in 10 to 15% of cases.10,41

Management. Reduction of the dislocation should be accomplished expeditiously, because the incidence of neurovascular complications increases with time.42 Radiographic documentation of the type of dislocation and any associated fractures should be obtained before attempting reduction. Reduction can be accomplished using various techniques, most of which involve traction, leverage, or scapular manipulation principles.43 No good comparative studies of one reduction technique over another have been conducted. The ideal method should be simple, quick, and effective; require little assistance; and cause no additional injury to the shoulder. It is wise to be familiar with several techniques of reduction, because none is uniformly successful.

Good muscle relaxation often is the key to a successful reduction. Occasionally, reductions can be accomplished without the use of any analgesia, especially if the time from injury to reduction is short or if the dislocation is a recurrent one. Muscle relaxation and analgesia also can be provided through intra-articular injection of a local anesthetic agent. This technique is especially useful when procedural sedation is contraindicated. Under sterile technique, the joint is entered 2 cm inferior to the lateral edge of the acromion using an 18-gauge or 20-gauge needle. Any associated hemarthrosis is aspirated; then 20 mL of 1% lidocaine is injected over 30 seconds. The patient is allowed to relax for 15 minutes before reduction is attempted. The published studies to date all have used lidocaine, although it would be reasonable to expect similar results with other local anesthetic agents such as bupivacaine.

Kuhn recently reviewed six randomized controlled trials comparing intravenous sedation and intra-articular lidocaine.44 Outcomes in these studies included success rates, complications, and time spent in the ED. Although the reduction techniques were not controlled in these studies, none showed a statistical difference in the reduction success rates, which averaged 92% for both the intra-articular lidocaine and intravenous sedation groups.44 Complication rates were quite different, however, averaging 0.9% in the intra-articular lidocaine group and 16.4% in the intravenous sedation group. In two studies, time spent in the ED was significantly less for the intra-articular lidocaine group.45

Gentle traction in various directions (forward flexion, abduction, overhead, lateral) is used to overcome the muscle spasm that holds the humeral head in its dislocated position.43 In the Stimson or hanging weight technique (Fig. 50-26), the patient is placed prone, with the dislocated arm hanging over the edge of the examining table. A 10- or 15-pound weight attached to the wrist or lower forearm provides traction in forward flexion. Reduction usually occurs over 20 to 30 minutes. In the traction-countertraction method (Fig. 50-27), traction is applied along the abducted arm while an assistant using a folded sheet wrapped across the chest applies countertraction. The forward elevation maneuver of Cooper and Milch also is simple and safe. The arm initially is elevated 10 to 20 degrees in forward flexion and slight abduction. Forward flexion is continued until the arm is directly overhead. Abduction is increased, and outward traction is applied to complete the reduction. Another simple and effective traction technique is the Snowbird technique, which has a reported success rate of 97%.46 In this method, the patient is seated in a chair, and the affected arm is supported by the patient’s unaffected extremity. A 3-foot loop of 4-inch cast stockinette is placed along the proximal forearm of the involved extremity with the elbow at 90 degrees. The patient is assisted or instructed to sit up, and the physician’s foot is placed in the stockinette loop to provide firm downward traction. The physician’s hands remain free to apply any gentle external pressure or rotation as needed until reduction is accomplished.

The most commonly recommended leverage technique is the external rotation method of Liedelmeyer.47 With the patient in the supine position, the involved arm is slowly and gently adducted to the side. The elbow is flexed to 90 degrees, and slow, gentle external rotation is applied to achieve reduction.
such as the Hippocratic method (traction with the foot in the axilla) and the Kocher maneuver (leverage, adduction, and internal rotation), are no longer recommended because of a high incidence of associated complications (axillary nerve injury, humeral shaft and neck fractures, capsular damage).

The neurovascular examination must be repeated and findings recorded after any attempt at reduction. It also is generally recommended that radiographic studies be repeated to confirm reduction and to identify any associated fractures not apparent on prereduction films.\textsuperscript{50-52} The study investigators did not find any new clinically significant fractures on postreduction radiographs and argued that in most instances, a successful reduction can be determined clinically by the presence of a palpable clunk, decrease in pain, and improvement in the range of motion. Reduction in the number of postreduction radiographs also decreases costs and shortens the ED throughput times.\textsuperscript{52} The findings on most of these studies are very subjective, however, and one cannot assume that all practitioners will have the same clinical acumen. Other studies show that as many as 7.5\% of fractures initially were detected only on postreduction films.\textsuperscript{53} Plain radiography of the shoulder is readily available and presents little or no risk to the patient. Unfortunately, failure to confirm reduction with radiographs and failure to diagnose all associated fractures could lead to malpractice claims. For these reasons, imaging of suspected shoulder dislocations remains

\textbf{Figure 50-27.} Traction-countertraction method for reducing anterior shoulder dislocations.

\textbf{Figure 50-28.} External rotation technique for reducing anterior shoulder dislocations. The involved arm is slowly adducted to the patient's side, and the elbow is flexed 90 degrees. Gentle external rotation is applied to the forearm to achieve reduction. (From Simon RR, Koenigsknecht SJ: Emergency Orthopedics: The Extremities, 2nd ed. Norwalk, Conn, Appleton & Lange, 1987.)

\textbf{Figure 50-29.} Proper hand position and direction of rotation during shoulder relocation using the scapular manipulation technique. Arrow indicates direction of applied force. (From Kothari RU, Dronen SC: The scapular manipulation technique for the reduction of acute anterior shoulder dislocations. J Emerg Med 8:625, 1990.)

\textit{Scapular manipulation} accomplishes reduction by repositioning the glenoid fossa rather than the humeral head and can be successful with minimal analgesia or muscle relaxation. The patient is placed in the prone position with the affected arm hanging off the table as for the Stimson technique. After the application of downward traction (manual or hanging weights), the scapula is manipulated by rotating the inferior tip medially (Fig. 50-29) while stabilizing the superior and medial edges with the opposite hand.\textsuperscript{48} McNamara\textsuperscript{49} also described a seated modification of the scapular method in which traction is applied in the forward horizontal position while an assistant manipulates the scapula. Scapular manipulation can be difficult in heavyset patients, in whom it is difficult to palpate and grasp the inferior tip of the scapula. More traditional techniques,
test, the patient will actively resist further external rotation and/or appear apprehensive. A lax or redundant anterior capsule is thought to be responsible for this syndrome, and recurrent episodes are common. These patients should be referred for orthopedic follow-up care because definitive therapy (capsulorrhaphy) is surgical.

**Posterior Dislocation**

**Pathophysiology.** Posterior dislocations are rare and account for 2% of all glenohumeral dislocations.58 This rarity is explained partly by the anatomy of the shoulder girdle. The 45-degree angulation of the scapula on the thoracic cage positions the glenoid fossa posterior to the humeral head, which serves as a partial buttress against posterior dislocation. More than 50% of posterior dislocations are missed on initial evaluation, and many remain unrecognized (“locked posterior dislocations”) for weeks or months.59,60

A posterior dislocation can result from several distinct mechanisms of injury. Convulsive seizures (epileptic or after electrical shock) have been associated with unilateral or bilateral posterior dislocations. In this instance, the larger and stronger internal rotator muscles (latissimus dorsi, pectoralis major, teres major, subscapularis) overpower the weaker external rotators (teres minor, infraspinatus) to produce the injury.59 A posterior dislocation also can occur after a fall onto the outstretched hand with the arm held in flexion, adduction, and internal rotation or after a direct blow to the anterior aspect of the shoulder. Acute posterior dislocations are classified into three types—subacromial, subglenoid, and subspinous—based on the final resting position of the humeral head. The subacromial variety accounts for 98% of all posterior dislocations.58

**Clinical Features.** Early diagnosis is essential to prevent long-term functional complications. As mentioned, the initial examining physician misses the diagnosis with some regularity, in part because of an overreliance on radiologic findings and an underreliance on the clinical examination. The most common misdiagnosis is adhesive capsulitis.58,60 The patient holds the affected arm across the chest in adduction and internal rotation. Although usually painful, the injury can be relatively painless.59 The normal shoulder contour is replaced by a flat, squared-off appearance, and the coracoid process is prominent and easily palpated. The humeral head may be palpable posteriorly beneath the acromion process. Abduction is severely limited, and external rotation is completely blocked.

**Diagnostic Strategies: Radiology.** Standard anteroposterior radiographs can appear deceptively normal with posterior dislocations. The common difficulty with identifying posterior dislocation in the frontal plane has led to the description of several characteristic radiographic features. Standard antero-
posterior films show loss of the half-moon elliptical overlap of the humeral head and glenoid fossa. In addition, the distance between the anterior glenoid rim and the articular surface of the humeral head is increased (the rim sign). The humeral head is profiled in internal rotation and takes on a “lightbulb” or “drumstick” appearance (Fig. 50-31). A true anteroposterior film shows abnormal overlap of the glenoid fossa with the humeral head (Fig. 50-32). Finally, an impaction fracture of the anteromedial humeral head (reverse Hill-Sachs deformity) is invariably present (see Fig. 50-32). This fracture may produce a curvilinear density on the frontal projection parallel to the articular cortex of the humeral head (the trough sign). An orthogonal view, such as an axillary lateral, transscapular (see Fig. 50-31), or apical oblique, confirms the diagnosis. The axillary lateral view or apical oblique view also identifies associated fractures of the humeral head and posterior glenoid rim. CT may be helpful in some instances.

Management. Orthopedic consultation should be obtained for all posterior dislocations. Closed reduction may be attempted in the ED with the patient under conscious sedation. The technique of reduction incorporates axial traction in line with the humerus, gentle pressure on the posteriorly displaced head, and slow external rotation. If this technique fails, reduction with the patient under general anesthesia is indicated.
After reduction, the shoulder should be immobilized in external rotation with slight abduction. Patients whose injury was missed initially and present with a chronic or locked posterior dislocation should be discussed with the on-call orthopedist. Locked posterior dislocations usually require open reduction and internal fixation or arthroplasty.

Complications. Fractures of the glenoid rim, greater tuberosity, lesser tuberosity, and humeral head account for most associated injuries. The subscapularis muscle rarely may be avulsed from its insertion site on the lesser tuberosity. Neurovascular injuries are uncommon because the anterior location of the neurovascular bundle protects it from injury. Recurrent posterior dislocations occur in 30% of patients and predispose the joint to degenerative changes.

Inferior Glenohumeral Dislocation (Luxatio Erecta)

Pathophysiology. Luxatio erecta is a rare type of glenohumeral dislocation in which the superior aspect of the humeral head is forced below the inferior rim of the glenoid fossa. Less than 1% of all shoulder dislocations are of this variety, and the mechanism of injury involves either indirect or direct forces. Most inferior dislocations result from indirect forces that hyperabduct the affected extremity. This causes impingement of the humeral head against the acromion process. Further levering of the humeral shaft against the acromion ruptures the capsule and dislocates the head inferiorly (Fig. 50-33). Application of a direct axial load to an abducted shoulder also can disrupt the weak inferior glenohumeral ligament and drive the humeral head downward.

Clinical Features. Clinically the patient has the arm locked overhead in 110 to 160 degrees of abduction. The elbow usually is flexed, and the forearm typically rests on top of the head. The shoulder is fixed in this position, and any attempts at movement result in significant pain. The inferiorly displaced humeral head may be palpable along the lateral chest wall. A thorough neurovascular examination is essential to evaluate for associated injuries.

Diagnostic Strategies: Radiology. Many cases of luxatio erecta are mistakenly diagnosed and treated as subglenoid anterior dislocations because the radiographic features of these two clinical entities are remarkably similar. Standard anteroposterior radiographs show the superior articular surface inferior to the glenoid fossa (Fig. 50-34). In addition, the humeral shaft characteristically lies parallel to the spine of the scapula on the anteroposterior view. This radiographic feature is useful in distinguishing luxatio erecta from a subglenoid anterior dislocation: In the latter, the humeral shaft lies parallel to the chest wall. Associated fractures of the acromion, coracoid, clavicle, greater tuberosity, humeral head, and glenoid rim are common.

Management. If possible, orthopedic consultation should be obtained before closed reduction using procedural sedation is attempted in the ED. Reduction usually can be accomplished by traction-countertraction maneuvers. The operator applies traction in line with the humeral shaft, while an assistant applies countertraction across the shoulder (Fig. 50-35). Gentle abduction usually reduces the dislocation, and the arm is brought down into an adducted position. Multiple attempts may be necessary; occasionally, “buttonholing” of the capsule

Figure 50-33. Luxatio erecta. A, The mechanism by which this injury occurs in hyperabduction. B, This is always accompanied by disruption of the rotator cuff and tear through the inferior capsule. (From Simon RR, Koenigsknecht SJ: Emergency Orthopedics: The Extremities, 2nd ed. Norwalk, Conn, Appleton & Lange, 1987.)

Figure 50-34. Anteroposterior radiographic view of an inferior glenohumeral dislocation. The humeral shaft lies parallel to the spine of the scapula.

Figure 50-35. Traction-countertraction method for reduction of luxatio erecta humeri. Arrows indicate direction of applied force and relevant movement. The initial maneuver (1) includes steady axial traction in line with the humeral shaft position, followed by gentle abduction. This reduces the glenohumeral dislocation. At this point (2), the arm is brought down to a position of adduction and internal rotation. (From Davids JR, Talbott RD: Luxatio erecta humeri. Clin Orthop 252:144, 1990.)
will prevent closed reduction, necessitating open reduction. An alternative approach is the two-step closed reduction maneuver, in which the inferior dislocation is first converted into an anterior dislocation before being reduced. The mechanism of injury involves a massive blunt force directed over the shoulder or severe traction force applied to the upper extremity. Approximately 50% of the reported cases involve motorcycle accidents, with the injury occurring when the motorcyclist hangs onto the handlebars while the body is forced away. The diagnosis is based on history, clinical findings, and radiologic studies. The injury often is overlooked at first, because most patients have multiple injuries that distract the treating physician. Massive local soft tissue swelling of the shoulder along with greater than 1 cm of lateral displacement of the scapula on the anteroposterior chest radiograph is pathognomonic for scapulothoracic dissociation. Associated osseous injuries include acromioclavicular separation, displaced fractures of the clavicle, and dislocations of the sternoclavicular joint. Vascular lesions have been reported in 88% of patients and severe neurologic injuries in 94%, so a thorough assessment for these injuries is essential. Outcomes generally are poor, with death in 10% of cases and only local analgesia or minimal procedural sedation.

Complications. Neurapraxic lesions of the brachial plexus are common, and thrombosis of the axillary artery has also been associated with luxatio erecta. Other associated injuries include tears of the rotator cuff and avulsion fractures of the greater tuberosity. Adhesive capsulitis is a common long-term complication of luxatio erecta.

Scapulothoracic Dislocation

Scapulothoracic dissociation is a rare and severe injury characterized by complete disruption of the scapulothoracic articulation and may be thought of as a partial or complete internal forequarter amputation. The mechanism of injury involves a massive blunt force directed over the shoulder or severe traction force applied to the upper extremity. Approximately 50% of the reported cases involve motorcycle accidents, with the injury occurring when the motorcyclist hangs onto the handlebars while the body is forced away. The diagnosis is based on history, clinical findings, and radiologic studies. The injury often is overlooked at first, because most patients have multiple injuries that distract the treating physician. Massive local soft tissue swelling of the shoulder along with greater than 1 cm of lateral displacement of the scapula on the anteroposterior chest radiograph is pathognomonic for scapulothoracic dissociation. Associated osseous injuries include acromioclavicular separation, displaced fractures of the clavicle, and dislocations of the sternoclavicular joint. Vascular lesions have been reported in 88% of patients and severe neurologic injuries in 94%, so a thorough assessment for these injuries is essential. Outcomes generally are poor, with death in 10% of cases and a flail anesthetic upper extremity in complete brachial plexus injuries. Many of these latter cases eventuate in upper extremity amputation.

Soft Tissue Conditions

Impingement Syndromes: Rotator Cuff Tendinitis, Subacromial Bursitis

Pathophysiology. *Rotator cuff tendinitis* and *subacromial bursitis* can be considered part of a pathophysiologic continuum whose endpoint is represented by complete rupture of the rotator cuff. These two conditions are common causes of shoulder pain and have similar clinical presentations. A key clinical feature is the presence of a painful arc sign (Fig. 50-36).

The subacromial space is the area between the coracoacromial arch and the greater tuberosity of the humerus. This space, which is only a few millimeters wide, contains the long head of the biceps, the rotator cuff, and the subacromial bursa. The bursa provides the gliding mechanism between the musculotendinous cuff and the coracoacromial arch. The functional arc of shoulder elevation is forward, which normally leads to impingement of the cuff and bursa under the anterior third of the coracoacromial arch. Similar impingement also occurs between 60 and 120 degrees of abduction and with the extremes of adduction. The critical wear from impingement is centered on the supraspinatus tendon, near its insertion on the greater tuberosity. Micro-opaque injection studies also have shown a relative avascularity within this “critical” area. The hypovascularity, in conjunction with repeated wear and age-related degenerative changes, ultimately results in rotator cuff tendinitis. Narrowing of the subacromial space (anatomic variants of anterior acromion) and occupations that require excessive overhead activity accelerate the entire process. With time, the inflammatory reaction spreads to involve the adjacent bursa. This inflammation leads to edema, thickening, and fibrosis, further narrowing the subacromial space (secondary impingement); this is eventually followed by attritional changes within the rotator cuff. Because the rotator cuff is a primary humeral head depressor, loss of function adds to the secondary impingement process.

The impingement process also may involve the long head of the biceps. In such cases, bicipital tendinitis, degeneration, or rupture may be present. If osteoarthritis of the ACJ has narrowed the subacromial space, the pathologic process can be accelerated. Impingement in this context occurs between 120 and 180 degrees of abduction (see Fig. 50-36).

Clinical Features. Neer classified the progressive pathologic processes into three stages (Table 50-2). Patients in stage I complain of a dull ache around the deltoid area after strenuous activity. On examination, tenderness can be elicited over the...
supraspinatus and anterior acromion. A painful arc of abduction between 60 and 120 degrees is characteristic. The Neer impingement sign (Fig. 50-37) has a sensitivity of 68% for all three stages. Several other tests have been described for the diagnosis of impingement syndrome. The combination of the Hawkins-Kennedy impingement sign (arm placed into 90 degrees of flexion followed by internal rotation), the painful arc sign, and the infraspinatus muscle test (resistance to internal rotation with arm adducted and elbow flexed to 90 degrees) provided the best post-test probability (95%) in one large clinical study.68

Stage 2 is characterized by more persistent pain that is particularly severe at night. The inflammatory process within the bursa and tendons leads to the formation of minor adhesions. Disruption of these adhesions is thought to account for the nighttime pain. Physical findings are similar to those in stage 1. In addition, bursal thickening leads to increased soft tissue crepitus within the glenohumeral joint. The hallmark of stage 3 is significant tendon degeneration after a prolonged history of tendinitis and bursitis. Findings in this stage are discussed in the subsequent section on tears of the rotator cuff. The radiographic appearance usually is normal in stages 1 and 2. Findings in stage 3 are similar to those with complete tears of the rotator cuff.

The differential diagnosis of impingement syndrome is extensive and includes intrinsic and extrinsic causes of shoulder pain. Extrinsic sources include the cervical spine, lung, heart, and diaphragm. Intrinsic conditions include acromioclavicular arthritis, adhesive capsulitis, calcific tendinitis, and traumatic anterior subluxation. A Neer impingement sign may be present in many of these other conditions. Relief of pain after the subacromial injection of 10 mL of 1% lidocaine (impingement test—see Fig. 50-37) helps localize the condition to the subacromial space.

Management. Initial treatment in stage 1 impingement syndrome is conservative and consists of rest, nonsteroidal anti-inflammatory drugs (NSAIDs), and modification of activities that produce impingement. In stage 2, emphasis is on maintaining flexibility and range of motion through physiotherapy and rotator cuff strengthening exercises. Patients with stage 1 and 2 disease who present to the ED reporting treatment failure with NSAIDs may benefit from a subacromial injection of corticosteroids (Table 50-3). Corticosteroid injections take 3 to 4 days for their full effect and must be injected accurately into the subacromial bursa.69 Patients with treatment-refractory stage 2 and stage 3 disease may require decompression surgery to control pain. Patients with stage 2 and 3 disease may benefit from referral to an orthopedist for more detailed evaluation and treatment.

Rotator Cuff Tears

Pathophysiology. The rotator cuff acts as a dynamic stabilizer of the glenohumeral joint. Its primary function is to hold the humeral head in place throughout the full range of motion (see Fig. 50-5). In addition, it contributes power in all directions and is responsible for specific movements. The infraspinatus and teres minor act as external rotators, whereas the subscapularis is an internal rotator. The supraspinatus is essential for the first 30 degrees of shoulder abduction.

The tenuous blood supply of the rotator cuff, abusive tensile overload, and chronic wear under the coracoacromial arch predispose it to age-related degenerative changes. The advanced stage of this process is characterized by complete rupture of the rotator cuff.

The role of impingement in the development of rotator cuff tears is controversial. Primary impingement (e.g., acromial variance) is uncommon but when present accelerates the

**Figure 50-37.** Impingement injection test. The impingement sign is elicited with the patient seated or standing and the examiner standing. Scapular rotation is prevented with one hand while the other hand raises the arm in forced forward elevation (arrow), causing the greater tuberosity to impinge against the acromion. This maneuver produces pain in patients with impingement lesions of all stages. It also causes pain in many other shoulder conditions. In the case of impingement lesions, the pain caused by this maneuver is relieved by the injection of 10 mL of 1% lidocaine beneath the anterior acromion. This test is useful in separating impingement lesions of all stages from other causes of shoulder pain. (Redrawn from Neer CS: Impingement lesions. Clin Orthop 173:70, 1983.)
degenerative process. More often, weakening or rupture of the cuff with age allows for superior migration of the humeral head, which results in secondary impingement. This impingement produces secondary changes within the subacromial space and symptoms characteristic of the impingement syndrome.

Rotator cuff tears typically involve the dominant arm and occur in men older than 40 years of age. The occupational history is significant for strenuous work requiring overhead activity. Most tears occur near the attachment of the supraspinatus and can extend anteriorly into the subscapularis or posteriorly into the infraspinatus. Tears can be classified according to their size, completeness, pattern location, or duration. A clinically useful system is to divide tears into acute or chronic types. Acute tears (10%) usually are associated with a specific traumatic event. Often no history of previous shoulder problems can be identified. The most common mechanism of injury is forced abduction associated with significant resistance; this usually occurs when the patient attempts to break a fall with an outstretched hand. Alternatively, the tendon rupture may occur with attempts to lift a heavy object or with a fall directly onto an immovable object.

**Clinical Features.** With acute tears, patients typically complain of a sudden tearing sensation in the shoulder followed by severe pain that radiates into the arm. Pain and secondary muscle spasm limit shoulder motion. Physical findings depend on the completeness, size, and location of the tear. Point tenderness is usually present over the site of rupture (greater tuberosity). A palpable defect also may be present. Subacromial injection of 10 mL of 1% lidocaine eliminates pain and allows for proper evaluation of motor function. The patient with a large tear cannot initiate shoulder abduction. A discrepancy between active and passive range of motion is highly suggestive of a rotator cuff tear. The drop-arm test, performed by passively abducting the arm to 90 degrees and asking the patient to hold the arm in this position, is positive with significant tears. Slight pressure on the distal forearm or wrist causes the patient to drop the arm suddenly. The acute pain resulting from hemorrhage and spasm subsides over a few days. Repeat examination at this point confirms the loss of function in significant tears.

Chronic tears account for approximately 90% of all lesions. Chronic tears are attritional and more insidious in their presentation. Early findings include the painful arc sign as a result of secondary impingement. The pain is worse at night and interferes with sleep. Worsening pain is followed by the gradual onset of weakness in the arm. Flexion and abduction are affected first. The patient attempts to initiate abduction using scapulothoracic movement. Internal rotation is weakened by anterior extension of the tear. Posterior extension compromises external rotation. The drop-arm test result is positive with large tears, and atrophy of the supraspinatus and infraspinatus muscles may be seen. In a large clinical study, the combination of the painful arc sign, drop-arm test, and positive infraspinatus muscle test results produced the best post-test probability (91%) for full-thickness rotator cuff tears.

**Diagnostic Strategies: Radiology.** Radiographs may be normal in acute and chronic tears, but more often they show evidence of nonspecific degenerative changes within the glenohumeral joint and subacromial space. The greater tuberosity can have a sclerotic or cystic appearance. Osteophytic spurs and sclerosis of the undersurface of the acromion may narrow the subacromial space. The hallmark of a complete tear is superior displacement of the humeral head. This displacement is best seen on an external rotation view. The normal distance from the superior aspect of the humerus to the undersurface of the acromion ranges from 7 to 14 mm. A distance of less than 6 mm is highly suggestive of a complete tear. Outpatient ultrasound examination, MRI, or an arthrogram can confirm the diagnosis. In a recent study, the overall accuracy of ultrasonography in the detection of partial- and full-thickness rotator cuff tears was 87%, using arthroscopy as the “gold standard” diagnostic modality.

**Management.** Acute tears should be immobilized in a sling and the patient referred promptly for orthopedic follow-up care. Early surgical repair (before 3 weeks) is preferred in these instances, especially for a young or active person. The management of chronic tears includes pain control and a shoulder rehabilitation program. Painful arc symptoms may respond to subacromial injection of a corticosteroid (see Table 50-3). Orthopedic follow-up care is essential because patients with persistent pain and weakness may require surgical repair.

**Lesions of the Biceps Muscle**

The biceps is composed of two heads. The long head originates from the supraglenoid tubercle and glenoid labrum and ascends over the humeral head to enter the arm by way of the bicipital groove. The long head is covered by a synovial sheath and is held in place within the groove by the coracohumeral and transverse humeral ligaments. The short head of the biceps originates from the coracoid process and inserts with the long head onto the tuberosity of the radius. The biceps is responsible for flexion as well as supination at the elbow and serves as a stabilizer for the glenohumeral joint.

**Bicipital Tendinitis**

Pathophysiology. Anatomically the long head of the biceps is subject to the same stresses as those incurred by the rotator cuff within the subacromial space. Irritation and microtrauma as a result of repetitive elevation or abduction of the shoulder produce an inflammatory reaction within the synovial sheath.
Bicipital tendinitis usually is associated with other acromial arch impingement conditions (e.g., subacromial bursitis, rotator cuff tendinitis). The typical patient is middle-aged and involved in an occupation or recreational activity that requires overhead movement. The presenting complaint is pain in the anterior part of the shoulder that radiates into the upper arm. The pain usually is initiated by some minor traumatic event involving forceful contraction of the biceps. Pain increases with activity and decreases with rest. Abduction and external rotation in particular are painful. Pain is worse at night and may interfere with sleep.

Primary bicipital tendinitis is uncommon (5% of cases) and affects much younger persons.72

**Clinical Features.** On examination, point tenderness can be elicited over the biceps tendon as it passes through the bicipital groove. This is best shown with the arm in 10 degrees of internal rotation. Active range of motion is limited by pain, but the passive range remains intact. Supination against resistance—the Yergason test—with the arm adducted and the elbow flexed to 90 degrees reproduces the pain in 50% of cases72 (Fig. 50-38). Another proactive test is the biceps resistance test (Speed test), in which forward flexion of the shoulder (elbow extended and forearm supinated) carried out against resistance produces pain in the bicipital groove.

**Diagnostic Strategies: Radiology.** Radiographic findings usually are unremarkable, and the confirmatory test of choice is an MRI study.

**Management.** The injured arm should be immobilized in a sling with the elbow in 90 degrees of flexion. The local application of ice may provide temporary relief. Analgesia should be provided, and the patient should be referred to an orthopedic surgeon within 72 hours for further evaluation and treatment. Surgical repair is a consideration in young, active persons. In older patients, conservative therapy (range-of-motion and strengthening exercise) is preferred because the cosmetic deformity is minimal and the mild functional loss usually is acceptable.

**Subluxations and Dislocations of the Biceps Tendon**

Subluxations and dislocations of the biceps tendon usually are associated with a congenitally shallow bicipital groove or attri- matic (attritional) tears of the coracohumeral and transverse humeral ligaments. The patient complains of a snapping sensation in the upper arm with abduction and external rotation. External and internal rotation of the abducted shoulder shows dislocation and relocation of the tendon. With complete dislocation, the arm may reflexively drop to relocate the tendon. These conditions may require operative repair and should be referred to an orthopedist.

**Calcific Tendinitis**

**Pathophysiology.** Ruptures of the biceps tendon can be classified into proximal and distal types. Distal ruptures are rare and are not discussed here. Proximally, microtears and other age-related attritional changes within the long head predispose it to rupture.70 The rupture can be spontaneous or may follow a traumatic event involving either forced extension or resisted supination and flexion.

**Clinical Features.** The classic history of an acute rupture is that of a sudden snap or pop, followed by pain and ecchymosis along the arm. The tendon usually ruptures at its weakest point, which is just distal to the exit from the glenohumeral joint cavity. With a complete rupture, distal retraction of the muscle results in a “Popeye” appearance of the arm. A difference in muscle contour (Ludington sign) also may be seen when both arms are placed behind the head and the biceps muscles are contracted.73 Functionally, forearm supination is weakened, but elbow flexion stays strong because the coracobrachialis and short head of the biceps remain intact. Most biceps tendon ruptures are associated with the impingement syndrome and a rotator cuff tear.

**Diagnostic Strategies: Radiology.** Radiographic findings usually are unremarkable, and the confirmatory test of choice is an MRI study.
the matrix of the tendon. Subsequent invasion of vascular channels into the deposit allows for the influx of neutrophils and macrophages (inflammatory response), which remove the calcification through phagocytosis. Finally, fibroblasts form collagen to create a postcalcification scar.  

Clinical Features. The clinical presentation can be divided into silent, subacute, and acute phases based on the physical characteristics of the calcific deposits and the nature of the inflammatory response within the tendon and subacromial bursa. The silent phase consists of a dry, powdery deposit with no surrounding inflammatory reaction. It usually is an incidental diagnosis when shoulder radiographs are obtained for other purposes. The deposits may remain painless and eventually reabsorb.

The painful arc syndrome is a hallmark of the subacute phase of calcific tendinitis. Enlargement and softening of the deposit lead to narrowing of the subacromial space, resulting in impingement under the acromial arch. Pain experienced between 60 and 120 degrees of abduction (see Fig. 50-36) is characteristic.

A severe inflammatory reaction within and around the deposit produces the acute phase of calcific tendinitis. The deposit becomes milky and has the appearance of an acute abscess. The patient is in severe pain and holds the arm close to the chest. Active and passive range of motion is severely limited. The shoulder is warm and extremely tender to the touch. Severe pain is related to increased intratendinous pressure, and spontaneous rupture of the deposit into the subacromial bursa can be associated with dramatic relief of symptoms.

Diagnostic Strategies: Radiology. Radiographs show calcific deposits in the involved tendon (Fig. 50-39). For the supraspinatus, calcific deposits are best seen on the internal and external rotation anteroposterior views. The axillary view is useful for showing calcification within the other tendons of the rotator cuff.

Management. Subacute symptoms usually respond to NSAIDs and measures to limit any offending activity. The acute phase should be treated with sling immobilization, NSAIDs, and analgesia. Subacromial injection of a local anesthetic may provide dramatic temporary relief in the ED. Needle lavage (puncturing of the calcific deposits to decrease intratendinous pressure in the operating room or under fluoroscopy) also has been described as an effective treatment during the acute phase. The subacromial injection of corticosteroids for impingement symptoms is controversial because these agents may delay the process of calcium resorption, thereby interfering with the natural course of the condition. Patients with chronic symptoms may benefit from extracorporeal shock wave therapy or surgical removal of the calcific deposit. Early shoulder range-of-motion exercises should be encouraged in all patients to minimize the risk of adhesive capsulitis. All symptomatic patients should be referred for orthopedic follow-up care.

Adhesive Capsulitis

Pathophysiology. Adhesive capsulitis (“frozen shoulder”) is a specific diagnostic entity characterized by an inflammatory reaction within the capsule and synovium of the glenohumeral joint. The inflammatory reaction results in the formation of adhesions within the capsule and inferior axillary fold, leading to restricted active and passive range of motion. The prevalence rate is 2%, with a female-to-male ratio of 58:42. The condition also is more common in diabetic patients. Adhesive capsulitis must be differentiated from other, more common causes of the painful stiff shoulder; this distinction is important because any painful condition of the shoulder (e.g., calcific tendinitis, rotator cuff tear, osteoarthritis, or trauma) may be associated with decreased range of motion. Although the cause of adhesive capsulitis is unknown, any condition associated with prolonged dependency of the arm can result in capsular contraction, including voluntary immobilization after calcific tendinitis, rotator cuff injury, mastectomy, or a distal upper extremity injury (Colles’ fracture).

Clinical Features. The typical patient is a diabetic woman between 40 and 60 years of age. The nondominant arm usually is affected, and the patient has trouble with the activities of daily living. The pain often is severe at night and localized over the deltoid area. There is uniform limitation of all glenohumeral movement, including flexion, abduction, and rotation. On passive testing, a sense of mechanical restriction of joint motion can be appreciated by the examiner. Shoulder radiographs usually are normal in appearance if no associated pathologic condition is present.

Management. The best form of therapy is preventive in nature. Prolonged immobilization must be avoided, and early motion of the shoulder should be encouraged in all instances (see Fig. 50-13). Treatment of adhesive capsulitis in the ED consists of NSAIDs and referral to an orthopedic surgeon. Initial therapy usually is conservative and consists of a gentle assisted exercise program along with intra-articular steroid injection. Surgical treatment, including manipulation under anesthesia and arthroscopic capsular release, is reserved for patients in whom at least 6 months of nonoperative treatment has failed to produce improvement.

Injection Therapy. The local injection of corticosteroid preparations can be useful in many painful conditions that affect the shoulder, including rotator cuff tendinitis and subacromial bursitis. Evidence-based research that supports or refutes the use of injection corticosteroid therapy is limited and conflicting. Potential explanations for discordant results of randomized controlled studies include differing outcome definitions and the observation that subacromial injections are difficult to give. The accuracy of needle placement for subacromial injections has been reported to be 70%. Although useful for relieving the inflammatory reaction, corticosteroid injections in general do not alter the underlying disease process. Corticosteroids inhibit all phases of the inflammatory response, including leukocyte migration, edema formation, mediator release, vascular permeability, collagen deposition, and fibroblast proliferation. Systemic complications are rare after local injection therapy. Site-specific complications include articular cartilage damage, tendon weakening or rupture, and subcutaneous atrophy. The incidence of local complications correlates...
with the injection technique, dose used, and frequency of administration. Direct tendon injection must be avoided at all times, and the number of steroid injections should be limited to two per shoulder since a high failure rate for rotator cuff repairs has been reported in patients who have received more than three preoperative subacromial injections.\textsuperscript{69}

Numerous corticosteroid preparations are available (see Table 50-3). Injection of a long-acting agent or a combination of a short-acting and a long-acting agent is preferred. The dose used depends on the size of the joint or bursa and the response of the individual patient. With concurrent use of a local anesthetic agent for acute pain relief, better diffusion of the steroid preparation may be obtained.

After injection, the shoulder should be immobilized, and activity should be limited for several days to protect against further injury. Improvement usually begins within 1 to 7 days and can last weeks to months, depending on the preparation and underlying condition. Local anesthetic injection may result in dramatic temporary relief of symptoms in the ED.

LOW BACK PAIN

■ PERSPECTIVE

Background
Approximately 70 to 90% of adults during their lifetime experience acute low back pain, defined as pain lasting less than 6 weeks in duration. The etiology for the back pain remains unknown in 85% of affected persons after appropriate initial investigation—a situation frustrating for both physician and patient. Frequent diagnoses in such cases include “acute lumbosacral strain,” “lumbago,” and “mechanical back pain.” These nonspecific, catch-all terms reflect the diagnostic challenge and lack of pathognomonic tests for low back pain. More accurately, these patients should be diagnosed with idiopathic low back pain. Regardless, most cases resolve spontaneously within 6 weeks. In recent studies on the management of acute low back pain, the most significant discovery—contradictory to traditional teaching from the 1980s—is the need to avoid bedrest for these patients, including those with sciatica symptoms. Management recommendations for chronic back pain remain controversial, however, and the condition accounts for a significant proportion of costs to the health care system.

Epidemiology
In the ambulatory care setting, the medical complaint of back pain is the fifth most common reason for a visit to a physician’s office, with 15 million annual visits in the United States. Low back pain primarily affects adults 30 to 60 years of age and has a tremendous impact on worker productivity, with significant economic consequences. In people younger than 45 years of age, persistent chronic back pain ranks as the leading cause of disability among chronic ailments. Among people 45 to 64 years of age, it ranks third, behind coronary disease and arthritis. It also is the second leading cause of pain resulting in lost productive time from work, following headache. Overall, patients with back pain account for billions of dollars in total direct and indirect costs in the United States.

The natural history of most cases of low back pain follows a benign and self-limited course. In a large pooled analysis, back pain decreases by 58% within 1 month. If the pain does not resolve within 3 months, however, it is unlikely to resolve after 12 months. The recurrence rate for pain is 66 to 84% within the first 12 months.

Risk factors for low back pain are continually being investigated. Data obtained so far have been inconclusive and often contradictory. It seems that the most consistent risk factor for future back problems is a history of previous back problems. Heavy lifting, pushing and pulling, or vibration at work; poor job satisfaction; smoking; and family history all seem to predispose to future back problems, whether causal or merely linked. Early evidence also points to a genetic predisposition to lumbar disk disease. Multiple other factors have been investigated, including body habitus, various occupations, and psychological profile, with conflicting results.

■ PRINCIPLES OF DISEASE

Anatomy and Physiology
The lumbosacral spine consists of five lumbar vertebrae and the sacrum. Moving from anterior to posterior, each vertebra can be divided into the cylindrical vertebral body, two pedicles, two transverse processes, two overarching laminae, and a spinous process. These structures surround the neural canal, which houses the spinal cord and nerve roots and has a mid-sagittal anteroposterior diameter of 15 to 23 mm. The paired superior and inferior articulating processes join the articulating process one vertebral level above and below. Each articulation site is called a facet joint. An intervertebral disk interposes between each vertebral body, providing elasticity and stability to the vertebral column. Each disk consists of an inner colloidal gelatinous substance, the nucleus pulposus, and an outer capsule, the annulus fibrosus, which is thinner posteriorly than anteriorly. Various ligaments and muscles also provide stability to the lumbosacral spine. The anterior and posterior longitudinal ligaments course along the anterior and posterior surfaces of the vertebral bodies. The posterior longitudinal ligament forms a border between the intervertebral disks and the neural canal. As expected, because this ligament thins as it runs inferriorly from L1 to S1, 95% of lumbar disk herniations occur at the L4–5 and L5–S1 levels, causing pain and neurologic deficit in the L5 to S1 distribution. Most herniations extrude posterolaterally to impinge a nerve root asymmetrically. The ligamentum flavum courses just anterior to the laminae within the neural canal. With age, this ligament can thicken, potentially causing spinal stenosis.

The spinal cord ends at the L1–2 interspace, and the lower cauda equina nerve roots extend inferiorly, exiting the sacral
Pathophysiology

Most conditions of low back pain have no proven cause. It is estimated that 85% of patients have no definitive diagnosis and are presumed to have pain originating from the soft tissue, including the muscles and ligaments. In the other 15% of patients with a known etiology, the pain may originate in the (1) nerve root, (2) articular facets, or (3) bone itself.

In low back pain of *nerve root origin*, a spinal nerve root can become inflamed and painful with external impingement. Disk herniation, usually at the L4–5 and L5–S1 levels, is the most common cause of *sciatica* (i.e., pain radiating down the posterior leg from sciatic nerve root irritation). As the disk starts to desiccate and degenerate, starting in their 30s, patients are at increased risk for outward herniation of the nucleus pulposus with consequent nerve root impingement. With further aging, these disks progressively shrink in size. In keeping with these findings, disk herniations typically are found in patients 30 to 50 years of age. Local nerve ischemia from physical compression also may contribute to the inflammation and pain. Studies also show that exposure of the nucleus pulposus during disk herniation may result in local neural inflammation, leading to pain. Nerve root impingement also can occur with spinal stenosis, a narrowing of the neural canal from congenital narrowing or, more often, from degenerative or hypertrophic changes of the disks, vertebrae, facet joints, and ligamentum flavum.

The two most critical conditions causing nerve irritation are cauda equina syndrome and a spinal epidural abscess. *Cauda equina syndrome* is most commonly due to a massive central disk herniation usually compressing multiple, bilateral nerve roots, causing back pain radiating to both legs, saddle anesthesia, and impaired bowel and bladder function. Emergent surgical decompression is indicated to preserve neurologic function. An *epidural abscess* similarly results in nerve root impingement, causing significant back pain. These rare infections develop most commonly from the hematogenous spread of *Staphylococcus aureus*.

Congenital and developmental spinal abnormalities also may cause back pain by nerve root inflammation in some cases, but much less frequently than was thought previously. Conditions such as kyphosis and scoliosis usually do not cause pain unless the degree of vertebral column misalignment is pronounced. Similarly, spondylolisthesis (slippage of one vertebral body on another) does not usually cause pain if the slippage is less than 25% of the vertebral body depth. Even in patients with higher grades of anterior slippage (anterolisthesis), the development of severe back pain is rare. Although it is one third as common as anterolisthesis, backward slippage (retrolisthesis) is almost always associated with back pain. Spondylolisthesis occurs most often at the L5–S1 level (82.1%), followed by the L4–5 level (11.3%) and the L3–4 level (0.5%). Multifactorial causes of spondylolisthesis include degenerative changes and trauma. Spondylolisthesis often is associated with bilateral pars interarticularis defects in the affected vertebra (spondylolysis).

In low back pain of *articular facet origin*, as with any other joint in the body, degenerative changes in the synovial articular facets in the lumbar sacral spine occur with age. Although the exact role and significance of articular facet joints in back pain are unclear, facet pathology for it has been suggested to contribute to 15 to 45% of chronic back pain cases.

In low back pain of *bone origin*, direct irritation of the vertebral bone and its peristemeum can cause back pain. The causes for spondylitis (osteoarthritis of the axial skeleton) can range from a slowly progressing tuberculosis infection (Pott’s disease) to a more acute bacterial infection. Typically, bacteria seed the bone from a hematogenous source, such as from a skin wound or urinary tract infection, or directly from intravenous drug use. The most common bacterial culprit is *S. aureus*. Primary and metastatic bone neoplasms can cause back pain from tumor infiltration into the bone. Primary bone tumors, such as multiple myeloma, chordoma, Ewing’s sarcoma, and osteosarcoma, are 25 times less frequent than metastatic disease. Of the neoplasms, breast, lung, prostate, thyroid, and kidney cancers and lymphoma are the most likely to metastasize to bone. Inflammatory conditions, such as ankylosing spondylitis and other arthropathies, and osteoporosis also can cause back pain. In osteoporosis, the generalized decrease in bone mineralization can cause pain from microfractures of the vertebral column.

![Figure 51-1. Lateral and axial views of lumbar vertebral anatomy.](image-url)
**Referred** pain, most commonly from intraperitoneal and retroperitoneal abdominal pathology, also must be considered in patients with back pain. Functional processes play a substantial role in back pain, especially for prolonged symptoms lasting more than 4 to 6 weeks. Functional causes range from fear, depression, and personality disorders to financial motivation. In such cases, no anatomic or pathophysiologic correlation with the reported pain can be found.

**Chronic back pain** is complex and multifactorial. Not only are the structural causes unclear, but the nonphysical factors are variable and difficult to determine. It is likely that many of these patients do have some kind of chronic pain. What is unknown is why chronic pain triggers depression, drug dependence, and malingering in some people but not in others. One difference may be the degree of disruption that the condition causes in the patient’s lifestyle. A normally active and athletic person who is incapacitated is more profoundly affected than someone who is habitually sedentary. Psychological factors and potential compensation play a large role in the behavior of many patients with chronic back pain.26,29

**Pediatric back pain** results in a diagnosis more often than adult pain.30,31 Children complaining of back pain require appropriate investigation. They may turn out to have spondylolysis with a variable degree of spondylolisthesis, Scheuermann’s disease (kyphosis and osteochondritis of the vertebral endplates), an infectious disease, or a neoplastic process. Disk herniation in children is comparatively rare, but when it does occur, the presentation is similar to that in adults.20

**CLINICAL FEATURES**

**Signs and Symptoms**

A thorough history and physical examination are crucial in evaluating all patients with acute low back pain. The classic historical (Table 51-1) and physical findings with various entities associated with low back pain are reviewed in this section. Although most of these etiologic disorders are benign, four such disorders have been identified by the Agency for Health Care Policy and Research as “cannot miss” or “red flag” diagnoses: spinal fracture, cauda equina syndrome, spinal infection, and malignancy.22 A methodical and focused approach to the history and physical examination can help assess the patient’s pretest probability for each of these disease entities and determine whether further tests should be ordered.

**Uncomplicated Musculoskeletal Back Pain**

Most patients with back pain can be classified in the category of those with uncomplicated musculoskeletal back pain, after exclusion of worrisome disease processes. Often, patients are unable to recall an inciting incident. The pain usually is characterized as an “ache” or “spasm” and is localized asymmetrically in the lumbar paraspinal muscle, with radiation to the buttckk or posterior thigh proximal to the knee. Movement exacerbates the pain, and rest relieves it. No associated deficit in sensation, strength, or bowel or bladder sphincter tone is identified in the history or on the clinical examination. The sole physical findings may be regional lumbosacral tenderness and a limited range of motion of the lower back. This diagnosis of exclusion is made only after ruling out the more worrisome causes of back pain.

**Radiculopathy**

Approximately 1% of all patients with low back pain exhibit signs of lumbar radiculopathy (i.e., nerve root irritation).23 The most common etiologic process is herniation of a lumbar disk; other causes include spinal stenosis, malignancy, and infection. The most common type of lumbar radiculopathy is sciatica—an L5 or S1 radiculopathy. Patients with sciatica describe their pain as radiating from the low back to the legs, distal to the knee. Such pain is characterized as “shooting,” “lancing,” “sharp,” or “burning.” Associated symptoms include numbness in one of the lower extremities. Exacerbating triggers include sitting, bending, coughing, and straining; relieving factors include lying supine and still.

On physical examination, the patient frequently exhibits tenderness to palpation in the sciatic notch. The **straight leg raise (SLR)** test is a fairly sensitive assessment tool to determine if the patient has sciatica. The SLR test is done with the patient supine and the legs extended. The symptomatic leg is passively raised while keeping the knee straight. The presence of back pain, which radiates past the knee when the leg is elevated 30 to 70 degrees, suggests an L5 or S1 radiculopathy. If the SLR test results in isolated low back pain without radiation symptoms to the legs, however, it is considered to be a **negative** finding. Through pooled analysis, the SLR test has a sensitivity of 91% but a low specificity of 26%, meaning that a negative result is fairly accurate in ruling out sciatica.24 Corroborative tests for sciatica include the “bowstring sign” (reproduction of pain with deep palpation of the taut “bowstring” posterior tibial nerve in the midline popliteal fossa) and

HIV, human immunodeficiency virus.
reproduction of pain with foot dorsiflexion when the leg is elevated just short of the pain threshold during the SLR test. As an alternative to the SLR test, with the patient in a seated position, the knee can be extended (“flip test”), which also should stretch the sciatic nerve. Reproduction of the pain often causes the patient to lean backward reflexively from the pain, almost “flipping” back into a supine position.

A crossed SLR test is done by passively raising the patient’s asymptomatic leg while keeping the knee straight. The presence of pain radiating from the back to the opposite affected leg has a sensitivity of only 29% but a high specificity of 88% for sciatica, meaning that a positive result on crossed SLR testing is almost pathognomonic for sciatica, whereas a negative result is nondiagnostic. A reverse SLR test is performed to detect L3 or L4 radiculopathy. With the patient prone, each hip is passively extended. If there is irritation of the L3 or L4 nerve root, pain is elicited.

In addition to stressing lumbar nerve roots, a thorough examination of the lower extremities detects subtle abnormalities associated with radiculopathies. This examination includes mapping the distribution of pain and assessing individual nerve root function, specifically strength, sensation, and reflexes. For the sensory examination, the earliest deficit can be detected by examining the most distal aspect of the dermatome. Specifically, light touch and pinprick sensation should be tested on the medial foot (L4), in the area between the great and second toes (L5), and on the lateral foot (S1) (Fig. 51-2).

**Herniated Disk**

Patients with herniated lumbar disks usually are 30 to 50 years of age and often have a long history of recurrent nonradicular low back pain, theoretically from irritation of the outer annular fibers of the disk. When the nucleus pulposus of the disk prolapses through the annulus fibrosus, local nerve root inflammation and radiculopathy result. Coughing, sitting, and any movement in general exacerbate the patient’s pain and radiculopathy symptoms. The severity of leg pain from radiculopathy often overshadows the back pain. Sciatica findings have a sensitivity of 95% for lumbar disk herniation, meaning that herniation is extremely unlikely in the absence of sciatica.

The physical examination should focus on lower extremity neurologic function and signs of radiculopathy. Weakness of ankle dorsiflexion, great toe extension, ankle plantar flexion, and knee extension is associated with respective specificities of 70%, 70%, 95%, and 99% for lumbar disk herniation.

**Spinal Stenosis**

Patients with spinal stenosis are typically older (mean age of 55 years) and constitute only 3% of all patients with low back pain. The classic history, identified in 60 to 75% of patients with spinal stenosis, is one of subacute or chronic pain and lower extremity radiculopathy that occurs with walking and is relieved with rest and, uniquely, bending forward at the waist. Because these symptoms mimic peripheral vascular claudication symptoms, pain from spinal stenosis is termed *pseudoclaudication*. Typically, vascular claudication lasts 5 minutes after resting, whereas pseudoclaudication lasts 10 to 15 minutes. Patients with spinal stenosis obtain symptom relief with spine flexion and bending forward because these maneuvers increase spinal canal diameter and reduce spinal cord tension. Similarly, sitting also helps to relieve the symptoms in these patients, in contrast with patients with herniated disks. A typical history describes walking uphill without pain but experiencing pain on walking downhill, when the back is extended.

On physical examination, most patients are found to have a lumbar radiculopathy at one or multiple levels and increased back pain with extension. Classically, patients with spinal stenosis walk with a slightly bent-forward position. To help differentiate spinal stenosis from vascular claudication, peripheral pedal pulses and ankle-brachial indices should be checked.

---

**Figure 51-2.** Physical examination findings for L3–S1 radiculopathy. The X marks the ideal location to test for sensation for each nerve root. C-SLR, crossed straight leg raise; R-SLR, reverse straight leg raise; SLR, straight leg raise.
Degenerative Spondylolisthesis

Most cases of spondylolisthesis, forward displacement of one vertebral body over another, are caused by degenerative changes. This condition is most prevalent in adults older than age 50 and occurs most commonly at the L4–5 and L5–S1 junctions. Two thirds of older patients with radiographically documented degenerative spondylolisthesis are asymptomatic. For patients with pain, bending, twisting, and lifting activities aggravate the symptoms. Radiculopathies, spinal stenosis symptoms, or both may coexist. On physical examination, clinical findings may include a loss of lumbar lordosis, a step-off along the midline spine if the spondylolisthesis is severe, tight hamstrings, or a radiculopathy.

Arthropathies

Inflammatory arthropathies, such as ankylosing spondylitis, rheumatoid arthritis, and psoriatic arthritis, all are associated with subacute and chronic low back pain. Patients with these conditions exhibit a decreased range of spinal flexibility. Commonly with ankylosing spondylitis, patients complain of morning back stiffness and pain relief with exercise. On physical examination, patients with inflammatory arthropathy (not just AS) may have nonspecific manifestations, such as decreased spinal mobility, sacroiliac joint tenderness, and decreased chest expansion.

Red Flag Diagnosis: Fracture

In all patients who have experienced significant blunt trauma to the back or only minimal trauma in the setting of osteoporosis, fractures of the spinal column must be considered. Among patients taking long-term corticosteroids, who are predisposed to the development of early osteoporosis, back pain had a specificity of 99.5% for a spinal fracture in one series. This subpopulation of patients must be assessed for a fracture despite the absence of trauma. On examination, tenderness along the midline spine and paraspinal muscles from concurrent muscle spasm usually can be elicited.

Red Flag Diagnosis: Cauda Equina Syndrome

Cauda equina syndrome results from a sudden compression of multiple lumbar and sacral nerve roots. Although it is an extremely rare presentation of back pain, it constitutes a neurosurgical emergency. The usual cause is a massive central disk herniation, but other potential etiologic disorders include spinal epidural abscess, hematoma, trauma, and malignancy. Patients with cauda equina syndrome present with back pain and multiple-level radiculopathies, often involving both legs. Difficulty with bladder or bowel function also may be a feature. Diagnostic dilemmas arise because patients can present atypically with equivocal neurologic compromise and only mild to moderate pain.

The most consistent examination finding in cauda equina syndrome is urinary retention. With a high sensitivity for this finding of 90%, this disease process is unlikely if the patient’s postvoid residual urine volume is less than 100 to 200 mL. Saddle anesthesia, sensory deficit over the buttocks, upper posterior thighs, and perineal area, frequently is an associated finding, with a sensitivity of 75%. In 60 to 80% of cases, the rectal examination reveals decreased sphincter tone.19

Red Flag Diagnosis: Spinal Infection

Epidural abscess and spondylitis (osteomyelitis of the vertebral bone) are two types of dangerous spinal infections. Patients at higher risk include injection drug users, alcoholics, immunocompromised patients (e.g., patients with human immunodeficiency virus, diabetes mellitus, chronic renal failure, or long-term corticosteroid use), the elderly, patients who have sustained blunt trauma to the back, patients with an indwelling catheter, and patients with a recent bacterial infection. With epidural abscess, approximately 20% of patients have no comorbid illnesses or risk factors. The most common bacterial culprit is S. aureus, spreading hematogenously from a remote site or from direct extension of a local infection, such as spondylitis or disk space infection. Less common culprits are streptococcal strains and enteric gram-negative bacilli. Patient history reveals back pain even at rest and subjective fevers. On physical examination, there is often tenderness to percussion over the spinous process near the abscess location. Spinal epidural abscess remains a diagnostic challenge because approximately 50% of the patients have no neurologic deficits, and 50% may be afebrile on initial presentation. With this subtle and often chronic presentation, many cases are misdiagnosed on initial presentation. Accordingly, an awareness of this entity as a possible cause of low back pain is important for prompt diagnosis of this neurosurgical emergency, which carries a mortality rate as high as 25%.38

With spondylitis, infection often begins as a subtle hematogenous seeding of the disk space, causing diskitis. Subsequent contiguous spread of the disk space infection causes vertebral endplate erosion, leading to spondylitis. As with epidural abscess, the most common bacterial culprit is S. aureus. Less commonly, enteric gram-negative bacilli and Mycobacterium tuberculosis (in Pott’s disease) are the infecting organisms. Injection drug users also are at risk for Pseudomonas spondylitis. The history typically reveals a more indolent course of back pain, with subjective fevers. The physical examination findings can range from nonspecific tenderness of the spine to radiculopathy and cauda equina syndrome. Similarly nondiagnostic, the presence of fever has a sensitivity of only 27 to 50% for spondylitis.19

Red Flag Diagnosis: Malignancy

Vertebral infiltration with a tumor can be caused by either a primary or, more commonly, a metastatic malignancy. Affected patients generally are older than 50 years of age and often complain of subacute or chronic back pain that is worse at night. Risk factors include a history of known cancer (98% specificity), unexplained weight loss (94% specificity), persistent pain despite bedrest (90% specificity), and pain lasting more than 1 month (81% specificity). On examination, these patients typically have mild to moderate spinal tenderness. Examination of the organs in which tumors are most likely to metastasize to bone, including breast, prostate, and lung, is indicated.

Referred Back Pain

Referred pain often is difficult to differentiate from pain originating from the lumbarosacral structures. It is vital, however, to make the distinction. A sudden onset of severe, “tearing” back pain is classically an aortic dissection. Abdominal pain radiating to the back may be due to a ruptured abdominal aortic aneurysm in an elderly patient with atherosclerotic disease. Alternatively, abdominal pain radiating to the back could be from pancreatitis in a chronic alcoholic. Unilateral paraspinal pain associated with fever and nausea in a young woman could indicate pyelonephritis. In all such cases, a thorough examination of the abdomen, genitourinary system, and cardiovascular system is essential. Pinpointing the primary cause of the pain may radically alter the therapy for the patient.
**Functional Back Pain**

Distinguishing functional pain from “real” pain often is difficult, but several clues can be elicited from the history. A prolonged history of nonanatomic pain complaints, vague pain descriptions without localization, multiple lawsuits over similar problems, and lack of coordinated care for a problem that otherwise seems to dominate the patient’s life all suggest that a search for a physical cause would be fruitless. In such cases, secondary gain for the patient’s complaints often is likely.

On physical examination, maneuvers can be performed to try to detect functional back pain, if a psychological overlay is suspected. The first recommended maneuver is performing the SLR test from the sitting instead of the supine position. Seemingly focused on the knee examination, the physician extends the patient’s knee; this physiologically reproduces the SLR by stretching the L5 and S1 nerve roots. A positive response includes reproduction of the patient’s pain and extension of the back while seated to decrease traction on the sciatic nerve. A positive result on SLR testing in the supine position but a negative result in the seated position, and vice versa, suggests a nonphysiologic cause for the pain.

A second sign is apparent superficial tenderness. Some patients, to impress the physician with their degree of pain, respond dramatically to superficial palpation. This response is atypical for patients with genuine back pain. Nondermatomal sensory loss and widespread nondermatomal pain complaints also are unlikely to be caused by physiologic processes.

Third, back pain should not be elicited by pushing down on the patient’s scalp against the cervical spine. This maneuver axially loads only the cervical and not the lumbar spine.

Fourth, a patient who generally overreacts during the examination probably is not giving a true reflection of the actual discomfort. All of these signs are believed to correlate well with psychopathy but have poor prognostic value. They are suggestive of malingering and functional complaints but are neither sensitive nor specific enough to rule out organic pathology.11,42

**Back Pain in the Elderly**

In elderly persons with back pain, musculoskeletal processes and disk herniation are less likely etiologic disorders. Instead, spinal stenosis and degenerative spondylolisthesis should be considered. Also, the incidence of more worrisome diagnoses, such as an osteoporotic fracture, spinal infection, and malignancy, is much greater in this patient population. Consequently, in these cases, the threshold for further investigation should be much lower.

**Back Pain in Children**

The likelihood of a congenital cause for back pain, such as leg-length discrepancy and spondylolisthesis, is greater for children than for adults. Spondylolisthesis is diagnosed most often in patients older than 10 years of age who are involved heavily in sports and complain of low back pain worsened with activity. In a retrospective study in an urban pediatric emergency department (ED) over a 1-year period, the most common causative disorders in patients with back pain complaints included direct trauma (25%), muscular strain (24%), sickle cell crisis (13%), idiopathic (13%), urinary tract infection (5%), and viral syndrome (4%). Age younger than 18 or older than 50 years

**INDICATIONS FOR PLAIN LUMBOSACRAL RADIOGRAPHS IN PATIENTS WITH LOW BACK PAIN**

- Age younger than 18 or older than 50 years
- Any history of malignancy or unexplained weight loss
- Any history of fever, immunocompromise, or injection drug use
- Recent trauma, other than simple lifting
- Progressive neurologic deficits or other findings consistent with cauda equina syndrome
- Prolonged duration of symptoms beyond 4 to 6 weeks

**DIAGNOSTIC STRATEGIES**

**Laboratory Evaluation**

In the absence of historical and physical findings suggesting “red flag” diagnoses for low back pain, laboratory evaluation is unnecessary. When a patient presents with back pain suggestive of a spinal infection or malignancy, however, laboratory studies may help with risk stratification. Specifically, a complete blood cell count, erythrocyte sedimentation rate (ESR), and urinalysis should be performed. Additional laboratory studies should be tailored to the patient’s history and physical examination. Liver function testing and determination of amylase or lipase level may be indicated to investigate abdominal complaints.

For a spinal infection, the ESR usually is elevated (above 20 mm/hour), whereas the serum white blood cell (WBC) count may or may not be elevated. In one study, 13 of 40 (32%) patients with a spinal epidural abscess had a falsely reassuring WBC count less than 11,000/µL. When patients are diagnosed with a spinal infection, blood should be drawn for cultures because a single strain, most commonly S. aureus, can be isolated in 50 to 90% of the cases. Performing a lumbar puncture to evaluate the cerebrospinal fluid is unnecessary and is relatively contraindicated because of the risk of seeding the fluid with bacteria.

For a bony malignancy, the ESR also usually is elevated, whereas the WBC may be equivocal. The hematocrit may be low secondary to anemia of chronic disease. Other additional helpful laboratory tests include measurement of alkaline phosphatase, prostate-specific antigen assay, and serum immunoelectrophoresis and urine testing for light chains (for multiple myeloma).

**Plain Radiography**

The utility of “screening” lumbosacral plain radiographs for all patients with acute low back pain is extremely low. Plain radiographs contribute little to patient management in the absence of concerning “red flag” findings and needlessly expose the patient to radiation. Most patients with back pain do not need radiographs. In those cases in which radiographs have been obtained, normal findings are usual, but incidental findings, which may or may not be the true cause of the patient’s pain, also are relatively common and may include spondylolisthesis, abnormal spinal curvature, disk space wedging, or degenerative changes. Currently accepted indications for radiographs in patients with back pain are listed in Box 51-1.

Patients with radicular symptoms suggesting a herniated disk do not require radiographs. In addition to being undetect-
able on plain radiographs, disk herniations resolve with conservative management in most cases.

If radiographs are obtained, anteroposterior and lateral views usually are sufficient in the ED, although many centers also prefer to obtain a coned-down lateral sacral view. Oblique views are not necessary except in children, in whom spondylolysis and spondylolisthesis may be more prevalent.46

On plain radiographs, spondylolisthesis, vertebral osteomyelitis, and vertebral metastatic disease have classic appearances. Spondylolisthesis (Fig. 51-3) is classified into grade 1 through grade 4 based on the severity of the anterior slippage of one vertebral body over another. Grade 1, which is often asymptomatic, involves less than 25% slippage. Grade 2 through grade 4 involves 25 to 50%, 50 to 75%, and at least 75% slippage, respectively.

Spondylitis (Fig. 51-4) is characterized by erosion of contiguous vertebral endplates and a shortened disk space height, best seen on the lateral view. Because the anterior subchondral vertebral bone and disk space are highly vascular, it follows that spondylitis has a predilection for these areas because of the hematogenous spread of infection. With more advanced disease, vertebral bone erosion and collapse may occur.

Vertebral metastatic disease (Fig. 51-5) can manifest as either a blastic (hyperdense) or a lytic (hypodense) lesion and has a predilection for the vertebral body and pedicles. In contrast with osteomyelitis, the intervertebral disk space is spared.

If a red flag diagnosis is of concern, a plain radiograph may rule out a fracture but may not be adequate to rule out other pathologic processes, such as cauda equina syndrome, spinal infection, and malignancy. For cauda equina syndrome, patients more often have normal or nonspecific plain film findings because the most common etiology is a central disk herniation. For spinal infection and vertebral malignancy, the sensitivity of a plain radiograph is only fair at 82% and 60%, respectively.45 In these cases, the patient subsequently should undergo MRI if there is a high clinical suspicion.

Computed Tomography and Magnetic Resonance Imaging

For assessment of fractures of the vertebral column, computed tomography (CT) is superior to MRI. In the case of a fracture, CT helps to elucidate the integrity of the spinal canal and the risk for spinal cord impingement. For all other red flag diagnoses—cauda equina, spinal infection, and malignancy—MRI is the definitive investigative modality. Its superior tissue resolution, especially of the spinal cord and intervertebral disks, and its capability of generating more accurate sagittal reconstructions make MRI the ideal imaging modality. MRI is able to differentiate subtle soft tissue pathology, such as a spinal epidural abscess (Fig. 51-6). No radiation exposure is incurred with MRI, whereas one CT scan of the spine exposes the patient to approximately 4 years’ worth of natural background radiation.47

Although disk herniation is easily visualized on MRI, patients with findings consistent with an uncomplicated disk herniation (i.e., without objective findings of motor or sensory deficit on examination) should not routinely undergo MRI imaging because of the self-limited nature of the disease in most cases. Overimaging in patients with lumbar radiculopathy may lead to an overdiagnosis of disk herniations because
Figure 51-5. Anteroposterior plain radiograph shows blastic infiltration of metastatic breast cancer to the pedicles of L3 to L5 (arrows).

Figure 51-6. Axial T2-weighted magnetic resonance imaging of Staphylococcus aureus L2 epidural abscess impinging the dorsolateral aspect of the spinal canal. CSF, cerebrospinal fluid. (Image contributed by Dr. Stephen Bretz.)

incidental MRI-documented herniations have been shown to occur in 28 to 33% of asymptomatic patients. The result may be unnecessary surgical intervention.9,48,21

Special Investigations

Unless a process other than uncomplicated back pain or disk herniation is suspected, other investigations are not required. MRI is the definitive test for most conditions. Radionuclide scans have been used for locating suspected malignancy, infectious foci, and occult fractures as in spondylolysis. Nuclear medicine scans are regarded as sensitive but nonspecific.

Differential Considerations

Nonspecific low back pain is in many ways a diagnosis of exclusion. In a typical patient, within the 18- to 50-year age range with acute low back pain and with no radiculopathy, previous malignancy, weight loss, or fever, the diagnosis is almost certainly uncomplicated musculoskeletal back pain. When the patient falls outside of the aforementioned parameters, a wide variety of diagnostic possibilities must be entertained.

Almost anything can cause low back pain. Box 51-2 presents an extensive list of diagnostic considerations, but it is useful to look at the most common and most serious causes of low back pain other than musculoskeletal lumbosacral pain. One of the most life-threatening causes of referred back pain is a leaking or ruptured abdominal aortic aneurysm. The reader is referred to appropriate chapters for further discussion of specific problems.

Management

Because most patients with acute low back pain without objective sensory or motor loss on examination experience symptomatic resolution within 4 to 6 weeks, only conservative management is needed. In general, MRI and surgery are reserved for the few patients who have worrisome systemic signs and patients with refractory, debilitating back pain. Over the past few decades, the accepted practice has shifted 180 degrees, from an overaggressive recommendation for invasive surgical intervention to the minimalistic recommendation of symptomatic pain control and early return to activity. The recommended role of the physician in back pain management is to obtain a correct diagnosis, rule out significant pathology, avoid excessive investigation, provide analgesia, and educate the patient.49 The management for various etiologic categories of disorders that may cause low back pain is summarized in Figure 51-7. For management of fractures and referred pain, the reader is referred to the appropriate chapters.

Uncomplicated Musculoskeletal Back Pain

Besides a thorough history and physical examination, no further investigations are required for uncomplicated low back pain. Only pain control and patient education are indicated. Aside from an initial parenteral opioid or nonsteroidal anti-inflammatory drug, most patients can be managed with oral nonsteroidal medications. Ibuprofen is an ideal choice because it is inexpensive, but various nonsteroidal anti-inflammatory drugs have been shown to have the same efficacy. It is unclear whether ibuprofen is superior to acetaminophen.50 Short-term opioids also occasionally are needed for breakthrough pain in the acute setting. Various other medications have been advocated, including benzodiazepines and other muscle relaxants. Based on the current conflicting literature, these medications probably do not provide a significant added benefit, but they do increase the incidence of side effects such as drowsiness and drug dependence.51 Corticosteroids have no role in the treatment of uncomplicated low back pain.

In terms of patient education, one of the outdated practices of back pain management was that physicians convinced patients that they were sick. This was done by overinvestigating, overtreating, putting patients to bed, and taking them off work. It now has been shown convincingly and repeatedly that all of those interventions are excessive. Instead, patients should be educated about why they are not undergoing radiographic studies of their lumbosacral spine or laboratory tests and should be reassured of the likely benign course of the pain. Most patients can be convinced by education and an explanation of radiation dosing. A typical lumbosacral spine series involves as much gonadal irradiation as that incurred with a daily chest radiograph for 5 or 6 years.52 Patients also are discouraged from the outdated recommendation of strict bedrest. Compared with patients who are prescribed strict

Bedrest, patients who remain active experience earlier resolution of pain and return to work sooner. Patients should be made aware, however, that the back pain has a 66 to 84% likelihood of recurring within 12 months.

Other supplemental treatment modalities have been shown to be of debatable efficacy in the management of acute and chronic low back pain. These include acupuncture, physiotherapy, chiropractic manipulation, massage, ultrasound, traction, and transcutaneous nerve stimulation.

**Lumbar Disk Herniation**

Like patients with uncomplicated low back pain, patients with disk herniations and radiculopathy do not benefit from strict bedrest. In the acute setting, these patients should receive analgesics, but further investigation with laboratory tests and radiographs is not necessary. Most of these patients experience symptomatic resolution within 6 weeks with conservative, nonsurgical management.

Corticosteroid injections into the epidural space have been advocated for sciatica in the belief that this treatment helps to relieve some of the inflammation associated with disk herniation. Although some reduction of symptoms may be obtained initially, no long-term benefit or reduction in the need for later surgery has been documented. The use of systemic steroids in back pain and disk herniation remains controversial. Although there is no proven benefit, the anti-inflammatory effects make empirical sense in the context of radiculopathy. A large retrospective review showed no definite benefit of systemic steroids in either setting, but the definitive trial is yet to be done.

When the pain from disk herniation persists for longer than 4 to 6 weeks, outpatient MRI is indicated. With a documented herniation, these patients may benefit from surgical discectomy although this remains controversial compared to conservative management. Other indications for surgery include intractable pain and worsening motor or sensory deficit. Although surgical patients tend to have earlier relief of pain compared with nonsurgical patients, the 4- and 10-year results are the same. Microsurgery techniques and laser therapy have not been shown to confer any advantage over conventional techniques.

**Spinal Stenosis**

Patients with spinal stenosis should be managed conservatively with pain medications. In the absence of alarming red flag findings, these patients do not require laboratory or radiographic studies in the ED. These patients may be candidates for surgery if they show any of the following conditions: pro-
gressive neurologic deficit, progressive reduction in ability to walk secondary to pseudoclaudication, evidence of cauda equina syndrome, or intractable pain. Elective surgical decompression is more controversial. A 10-year longitudinal study showed that no findings predicted which patients would benefit more from surgery than from conservative management.62 The benefits of surgery also must be weighed against the risks of surgery itself, because these patients usually are elderly.

Degenerative Spondylolisthesis

Patients with symptomatic degenerative spondylolisthesis are managed conservatively with analgesia and lifestyle changes, which include the avoidance of repetitive bending, heavy lifting, and twisting at the waist. For patients with refractory or severe back pain, outpatient MRI and neurosurgical referral for possible operative decompression are recommended.

Red Flag Diagnosis: Fracture

See Chapter 40, Spinal Injuries.

Red Flag Diagnosis: Cauda Equina Syndrome

Cauda equina syndrome is a neurosurgical emergency that requires urgent operative decompression to help preserve distal neurologic function. All patients with concerning findings, such as saddle anesthesia or a large postvoid residual volume, require emergent MRI. On average, outcome is improved if decompression takes place within 48 hours of symptom onset.63 Early evidence, however, indicates that delayed operative decompression under a more controlled setting may be performed without any adverse effects, particularly in patients who have overflow urinary incontinence.64

Red Flag Diagnosis: Spinal Infection

If findings on the history or physical examination are worrisome for a spinal infection, further investigation is of paramount importance. With a low index of suspicion, normal results on serum WBC count, ESR, and lumbosacral plain radiograph can safely rule out infection. The patient’s history and examination are worrisome for spinal infection and further investigation is paramount. In patients with moderate to high pretest probability for a spinal infection, the next step is to obtain an emergent MRI.

Pyogenic spinal infections should be treated with neurosurgical drainage and decompression, in addition to broad-spectrum intravenous antibiotics that cover at least for S. aureus and gram-negative bacilli until blood culture results return. Vancomycin should be included in the antibiotic regimen, given the increased prevalence of methicillin-resistant S. aureus. For injection drug users, antibiotic coverage for
Pseudomonas is necessary. The recent literature suggests that a nonsurgical management approach may be acceptable for patients at lower risk, such as those who are hemodynamically stable and neurologically intact. 65

**Red Flag Diagnosis: Malignancy**

An algorithmic guideline to the management of back pain that is worrisome for malignancy involves subdividing patients into two categories: patients with and patients without a history of previous cancer. Development of spinal metastasis has been reported in 20 to 85% of patients with cancer. 66,67 These patients are subdivided further into those with and those without evidence of a radiculopathy.

Most patients fall into the classification of back pain without a history of cancer and without a radiculopathy. They have a history that is only suggestive of a malignancy, such as unexplained weight loss or back pain that is worse at night. These patients require further risk stratification with plain radiographs and laboratory tests, including a complete blood cell count and ESR. With normal results, these patients can be referred to their primary care physician for further workup. The physician should not feel completely reassured that malignancy has been ruled out, however, because plain films have a false-negative rate of 10 to 17% for vertebral bone metastasis. This false-negative rate is likely to be due to the fact that a cancer needs to erode at least 50% of the bone before becoming radiographically apparent. 68 With abnormal results, such as a bone lesion or extremely elevated ESR level (above 100 mm/hour), an urgent CT scan or MRI should be performed on an outpatient basis within the next 3 to 7 days.

For patients without a history of cancer but with signs of radiculopathy, the workup also includes a plain radiograph, complete blood cell count, and ESR. If the test results are normal, the patient should be referred to his or her primary care physician for further evaluation for malignancy and other potential causes of radiculopathy, including spinal stenosis and disk herniation. If the workup shows a bone lesion on plain radiographs or an extremely elevated ESR level (greater than 100 mm/hour), the patients should undergo emergent MRI because (1) the presence of radiculopathy may be an early harbinger of impending spinal cord compression from a mass effect and (2) it often is difficult on plain radiography to distinguish between a neoplasm from early spondylitis (especially tuberculous osteomyelitis) and an osteoporotic fracture causing a vertebral collapse. 69 If MRI is unavailable, multidetector CT imaging can be performed initially to screen for the presence of malignant bone infiltration, although definitive spinal cord and nerve root imaging will require MRI. The presence of a vertebral mass lesion on CT images suggests spinal cord compression by the mass as a cause for the pain and other symptoms.

For patients with a history of previous cancer and low back pain, advanced imaging is indicated, either emergently or urgently within 3 to 7 days. In the absence of clinical manifestations of radiculopathy, these patients should undergo outpatient MRI (or CT) regardless of plain radiography findings and laboratory results. Plain radiography is too insensitive to rule out a vertebral neoplastic process definitively. If radiculopathy is present, however, these patients require emergent MRI regardless of plain radiography findings because of the concern for spinal cord compression. In a study of patients with a confirmed diagnosis of cancer who had back pain and radiculopathy, the risk of epidural spinal cord compression was 25% despite normal radiographic findings, and 88% with radiographic evidence of vertebral metastasis. 70

In all patients undergoing emergent MRI to evaluate for vertebral malignancy and cauda equina syndrome, dexamethasone should be administered as soon as these conditions are suspected to reduce the potential mass effect. In addition to high-dose corticosteroids, patients with a vertebral neoplasm also may benefit from radiation therapy.

**Pediatric Back Pain**

Management of back pain in children is similar to management for adults and depends on the underlying causative disorder. Spondylolisthesis is managed by observation, with only 4 to 5% of cases worsening. Progression usually stops as skeletal maturity is achieved in the late teens. Current recommendations are for limited contact sports in children with less than 30 to 50% slippage and surgical stabilization for children with slippage greater than 30 to 50%. Treatment becomes more aggressive if the child is symptomatic. 71

**Chronic Back Pain**

Patients with chronic back pain often are regarded as the most challenging of all patients with back pain. The cause of chronic back pain is complex and multifactorial and usually requires a multidisciplinary approach for the greatest chance for success. Psychosocial factors, including depression, drug dependence, and financial gain, undoubtedly play a significant role in the behavior of many of these patients, making proper assessment and treatment impossible in the ED.

After appropriate evaluation has ruled out a red flag cause for the back pain, ED management involves analgesia and referral for follow-up care. The main decision usually centers on the use of narcotics, which should be individualized in accordance with the physician’s assessment of the clinical scenario. Patients exhibiting drug-seeking behavior classically are from out of town, have a primary care physician who cannot be contacted, or are reportedly allergic to all nonopioid medications.

### DISPOSITION

Almost all patients with uncomplicated back pain can be discharged from the ED with follow-up with their primary care physician. In rare circumstances, severe pain or inadequate support for convalescence at home may preclude discharge. For patients who have a red flag diagnosis of cauda equina syndrome or epidural abscess, immediate neurosurgical consultation is required for emergent surgical decompression. For patients with spondylitis, hospitalization will be necessary for administration of intravenous antibiotics. With intractable pain from vertebral malignancy, the decision to hospitalize the patient for pain control, administration of high-dose corticosteroids, and radiation therapy should be made in conjunction with a neurosurgeon, an oncologist, and a radiation therapist.

One of the most important aspects of management of low back pain is the discharge instructions for the patient. Not only are clear and simple instructions useful to the patient, but they also constitute a medicolegal necessity for the physician. Physicians are advised to avoid using purely medical terms. The discharge instructions should include the following:

1. **Diagnosis:** Distinguish between uncomplicated (musculoskeletal) back pain and diskogenic radiculopathy.
2. **Activity:** Recommend maintaining active mobility as limited only by pain, avoiding heavy lifting until symptoms resolve, and getting back to full activity as soon as possible.
PART II

■ Trauma
Section three

• Orthopedic Lesions

equal gender distribution. Surgery for thoracic disks accounts for thoracic spine, cause pain and neurologic symptoms in much higher number of centrally herniated disks, resulting in much more frequent myelopathic symptoms.

UPPER BACK PAIN

■ PERSPECTIVE

Background
Thoracic pain is far less common than low back pain. Thoracic pain usually has a musculoskeletal origin, but other, more emergent causes must be considered first, including thoracic aortic dissection, pulmonary embolism, and esophageal disease. Compared with lumbar disk herniation, which is fairly common, thoracic disk disease is extremely rare, difficult to diagnose, and difficult to treat.

Epidemiology
The actual incidence of thoracic pain is unknown. The incidence of symptomatic thoracic disk disease is low, with estimates at 1 in 1 million. The average age is in the 40s with equal gender distribution. Surgery for thoracic disks accounts for less than 4% of all disk operations. Metastases are more common in the thoracic spine than in the lumbar spine, with 60 to 70% of spinal metastases localizing there.

■ PRINCIPLES OF DISEASE

Anatomy and Physiology
The thoracic vertebral column can be regarded as an extension of the cervical column with the addition of ribs. There are 12 thoracic vertebrae, connected by the anterior and posterior longitudinal ligaments and the ligamentum flavum, similar to the lumbar vertebrae. Also similarly, intervertebral disks provide elasticity and stability to the thoracic column. The spinal canal diameter remains unchanged through the thoracic and lumbar levels, but at the thoracic level, the space around the spinal cord is smaller than at the lumbar level. Because lumbar nerve fibers have not yet branched off from the spinal cord, the thoracic cord is thicker than the lumbar cord. Significant neurologic abnormalities may result from minimal spinal canal impingement at the thoracic level.

Pathophysiology
Common thoracic soft tissue pain is likely to be a combination of sprain and muscle inflammation. As in the lower back, innervation of the paravertebral area is provided by the sinuvertebral nerve, and any anatomic disruption of surrounding structures results in nonspecific pain. Thoracic disk herniations, which most commonly occur in the midthoracic to lower thoracic spine, cause pain and neurologic symptoms in much the same way as for lumbar disks. It is not clear why the clinical presentation is so varied, although a possible cause is a higher number of centrally herniated disks, resulting in much more frequent myelopathic symptoms.

■ CLINICAL FEATURES

Symptoms and Signs

History
Nondiskogenic thoracic back pain usually manifests as paraspinal discomfort. A history of trauma or recent unusual activity may or may not precede the onset of pain. Complaints with thoracic disk herniations are variable but usually are associated with long-standing pain or neurologic symptoms, or both. Pain may be localized to one part of the thoracic vertebrae, it may radiate down to the sacrum, or it may have a radicular component along the ribs. Central disk herniation can manifest as diffuse abdominal and back pain or burning sensation in the lower extremities. Associated findings may include mild weakness, spasticity, gait disturbance, bowel or bladder dysfunction, and paraesthesia. These usually progress until the condition is diagnosed. Because of the variable and often subtle signs and symptoms, thoracic disk disease typically is not diagnosed until 20 months after the first clinical presentation. Pain from other causes should be sought in the initial assessment. A history of trauma, fever, previous malignancy, cardiovascular disease, or gastrointestinal problems may indicate problems originating outside the thoracic spine and may warrant further investigation.

Physical Examination
In patients with benign musculoskeletal pain, the physical examination fails to disclose evidence of a pathologic process. These patients may experience mild to moderate paraspinal tenderness to palpation, pain with motion, and even discomfort from chest wall expansion with respirations, but objective findings are minimal.

Physical findings in patients with thoracic disk herniation will vary with the location and degree of herniation. Objective findings may range from a normal-looking spine to loss of posterior column function (position, touch, vibration) or unilateral or bilateral weakness. Gait and sensory abnormalities are common. Hypotonic abdominal reflexes may be present with distal hyperreflexia. A Babinski response may be present. Myelopathy may result in urinary retention. Muscle wasting may be present with chronic symptoms. The possibility of other pathologic conditions should be kept in mind during the physical examination, with appropriate assessment tailored to the presentation and level of clinical suspicion.

■ DIAGNOSTIC STRATEGIES

Laboratory Evaluation
In the face of an unremarkable history and physical examination, the likelihood that laboratory evaluation will yield useful results is extremely small. In appropriate clinical circumstances, assessment for malignancy, infection, and inflammation should be undertaken.

Radiology
The usefulness of radiologic assessment is dubious in a patient with atraumatic acute thoracic back pain in whom preexisting illness or neurologic abnormalities are absent. As a general
guide, however, the following factors should prompt basic radiologic studies and appropriate further investigations: clinical suspicion for presence of other conditions; unexplainable symptoms; extremes of age; concern for trauma, tumor, infection, gastrointestinal pathology, or vascular pathology; and prolonged symptoms. Like patients with lower back pain, patients with a history of cancer and upper back pain should undergo plain radiography and possibly CT or MRI to assess for vertebral metastatic disease, especially because metastases have a predilection for the thoracic spine.

MRI has become the modality of choice for evaluating a herniated thoracic disk. The incidence of asymptomatic disk herniations seen on MR images is 37%. Most herniated thoracic disks, whether symptomatic or not, have been reported to recede spontaneously. 72

**DIFFERENTIAL CONSIDERATIONS**

Although muscular back pain is extremely common, Box 51-3 summarizes the important considerations in the expansive differential diagnosis for thoracic back pain.

**MANAGEMENT**

Commonly, thoracic musculoskeletal pain is managed with analgesia. No studies have shown the need for any difference in management from that for musculoskeletal low back pain.

Thoracic disk disease is difficult to diagnose and manage. Symptomatic pain management and outpatient follow-up care are recommended. In view of the limited space in the spinal canal at the thoracic level compared with the lumbar level, spinal cord compression from a herniated disk is more likely at the thoracic level. Any disk herniation that precipitates an acute neurologic deficit warrants MRI and early neurosurgical evaluation.

**DISPOSITION**

Patients with benign back pain in any part of the thoracic vertebral column can be discharged with referral for follow-up care by the primary care physician. Patients with a suspected thoracic disk herniation require close outpatient follow-up. Most cases of subjective discomfort resulting from thoracic disk disease without objective neurologic findings resolve spontaneously, with one study showing a 77% improvement rate. 72 Although clear guidelines are lacking for when emergent neurosurgical consultation is required for thoracic disk herniation, patients with significant pain or neurologic compromise should be assessed rapidly.
Patients with traumatic pelvic ring injury may represent an immense challenge for the emergency physician. First, patients with pelvic ring fractures are at risk for exsanguinating pelvic hemorrhage. Furthermore, the profound magnitude of force required to disrupt the pelvic ring frequently causes severe injuries to other organ systems. The resuscitation from hemorrhagic shock, rapid identification of other major injuries and sites of blood loss, and the coordination of definitive angiographic and surgical treatments are paramount to achieving good clinical outcomes.

Epidemiology
The majority of high-energy pelvic ring injuries are caused by motor vehicle collisions (MVCs), motorcycle crashes, and pedestrians being struck by motor vehicles. Together, these account for 80 to 84% of pelvic fractures. Falls from height account for 5 to 12% of pelvic fractures.1-5 The mortality rates reported in the literature associated with pelvic fracture range from 9 to 22%.1-5; however, those patients who present with shock on arrival to the hospital have mortality rates between 33 and 57%.3,4 Increased age, shock on arrival at the hospital, high injury severity and revised trauma scores, and the need for transfusion have all been shown to increase the risk of death.3-6

Knowledge of the ligamentous attachments of the pelvic ring is crucial to understanding how stability is maintained or disrupted in pelvic injury. The stability of the pelvis is maintained by ligaments, as well as the muscles and fascia that make up the pelvic floor. Anteriorly, the symphysis pubis provides the major mechanical stability. Posteriorly, a complex of strong ligaments—the sacrospinous, sacrotuberous, iliolumbar, and anterior and posterior sacroiliac (SI) ligaments—maintains the integrity of the posterior arch (Fig. 52-2). It is important to appreciate that mechanically unstable pelvic fractures are unstable primarily because of the disruption of these posterior ligaments.

Vascular
Most of the blood supply to the pelvis comes from the left and right internal iliac arteries. The internal iliac arteries course at the level of the SI joints. The various arteries that derive from the internal iliac arteries initially run in close proximity to the posterior pelvic arch and eventually anastamose extensively with one another, forming a rich collateral network (Fig. 52-3). The superior gluteal artery is the largest branch and is commonly injured in fractures of the posterior pelvic arch. The obturator and internal pudendal branches are often injured in fractures involving the pubic rami.

The venous system also has many collateral branches and is without valves, allowing bidirectional flow. The veins are arranged in a plexus that adheres closely to the pelvic walls. Because these veins are thin-walled, they do not have the ability to constrict in response to damage. This anatomic arrangement of the arteries and veins accounts for the hemorrhage often seen with pelvic fractures. It is important to note that an intact peritoneum helps to tamponade and limit bleeding to the retroperitoneal space.
**Figure 52-1.** Bony pelvic anatomy. A, Anterior view of pelvis. B, Lateral view of right innominate bone. (1) iliac fossa, (2) iliac crest, (3) anterior superior iliac spine, (4) anterior inferior iliac spine, (5) symphysis pubis, (7) superior ramus of pubis, (8) inferior ramus of pubis, (9) ramus of ischium, (10) ischial tuberosity, (11) obturator foramen, (12) ischial spine, (14) acetabulum ([14a] articular surface, [14b] fossa), (15) sacrum, (16) anterior sacral foramina, (17) sacroiliac joint, (18) anterior sacroiliac ligament, (20) coccyx, (26) arcuate line, (27) posterior or femorosacral arch, through which main weight-bearing forces are transmitted, (28) anterior arch.

**Figure 52-2.** A, Anteroposterior view of the pelvis indicates that the sacrospinous ligament is a triangular strong ligament lying anterior to the sacrotuberous ligament, which is a strong broad band extending from the lateral portion of the dorsum of the sacrum to the ischial tuberosity. B, The major posterior stabilizing structures of the pelvic ring, that is, the posterior tension band of the pelvis, include the iliolumbar ligament, posterior sacroiliac ligaments, sacrospinous ligaments, and sacrotuberous ligaments.

**Figure 52-3.** The internal iliac plexus of arteries and veins. (From Tile M: Fractures of the Pelvis and Acetabulum, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 2003.)

**Neurologic**

The cauda equina courses through the sacral spinal canal and exits through the sacral neural foramina to form the lumbar and sacral plexus. Injury to the posterior bony pelvis and sacrum may result in neurologic deficits in the lower extremities and autonomic dysfunction involving the bowel, bladder, and genitalia.

**Pathophysiology and Key Patterns of Pelvic Fracture**

Numerous classification schemes exist for pelvic fractures. Two widely used schemes for pelvic injury are presented here. The classification by Tile stresses the biomechanical stability of the pelvic ring (Box 52-1). The Young-Burgess classification emphasizes the mechanisms of injury (Box 52-2). From a practical viewpoint, it is highly useful to consider both of these elements in the assessment of a pelvic ring fracture. For the emergency physician, a good understanding of both the underlying principles of pelvic stability and mechanisms of injury is far more important than a detailed knowledge of the
Normal pelvis is not totally rigid because of the slight mobility of the pelvic ring. Drugs for pain control (Fig. 52-4). Most stable pelvic fractures heal well with rest and analgesic drugs for pain control. These injuries are rotationally unstable but vertically stable.

**Type C**—Unstable, complete disruption of the posterior arch
Includes iliac, sacroiliac, and vertical sacral injuries that result from vertical shearing forces. May be unilateral or bilateral. These injuries are both rotationally and vertically unstable.

**Stable Injuries (Tile Type A)**
Fractures of individual bones without involvement of the pelvic ring represent one third of all pelvic fractures. In general, most stable pelvic fractures heal well with rest and analgesic drugs for pain control (Fig. 52-4).11

**Undisplaced or Minimally Displaced Fractures of the Pelvic Ring.** The normal pelvis is not totally rigid because of the slight mobility at the SI joints and symphysis pubis and the inherent elasticity of bone. A single break in the ring is possible. Nevertheless, the pelvis is not totally forgiving, and identification of a single break in the ring should prompt a search for a second disruption.

An isolated fracture of the superior or inferior pubic ramus is the most common pelvic fracture. These fractures are stable. They are common fractures in elderly people after a fall and must be considered in the evaluation of an acutely painful hip. Fracture of the body of the ischium is a rare injury that may result from a fall in the sitting position. These fractures around the obturator foramen are treated conservatively with bedrest, analgesia, and early mobilization.

Fracture of the superior and inferior pubic rami on the same side is a commonly encountered injury after a fall or MVC. These are generally stable fractures and are treated conservatively. However, the presence of significant displacement at the fracture site always indicates a second disruption elsewhere in the pelvic ring that must be diagnosed. Alternatively, fractures of both rami on the same side may be associated with an unrecognized impact fracture of the posterior pelvis.

If the patient with a ramus fracture complains of posterior pelvic pain and plain radiographs do not reveal posterior injury, further investigations may reveal occult posterior fractures. A study performed more than 30 years ago found that patients who sustained apparently isolated pubic ramus fractures showed increased uptake of radionuclides on bone scans in the acetabulum and SI joint, suggesting that occult bony or ligamentous injury accounted for the complaints of pain.15

More recently, a study that prospectively evaluated elderly patients who were diagnosed with isolated ramus fractures on plain films found that 95% had sacral fracture detected by magnetic resonance imaging.14

Also termed a straddle fracture, four-pillar injuries refer to fractures of both pubic rami on both sides of the symphysis pubis, causing the so-called butterfly segment (Fig. 52-5). The injury is produced by a direct blow with a straddle mechanism. Although these fractures may occur without posterior arch disruption, four-pillar injuries are also commonly associated with lateral compression or vertical shear forces that may cause concomitant injuries to the posterior pelvic arch. CT of the pelvis is required in cases of four-pillar injuries to detect and
classify precisely the posterior arch injury and plan orthopedic treatment. The genitourinary tract frequently is injured concomitantly with this type of pelvic fracture and must be evaluated carefully (see Fig. 52-5).

Isolated fracture of the iliac wing was described by Duverney in 1751 and now bears his name. It is caused by direct trauma to the iliac crest, usually by lateral compression forces. Although displacement is usually minimal because of the arrangement of the muscle attachments of the abdominal wall, orthopedic consultation is recommended. The fracture may extend into the acetabulum, altering the treatment and prognosis. Severely displaced fractures of the iliac wing require open reduction and internal fixation.

Transverse Fractures of the Sacrum. These injuries do not compromise the pelvic ring. Transverse fractures at or below S4 are unlikely to be accompanied by neurologic injury. An upper sacral transverse fracture is the result of a flexion injury, such as being struck on the lower back by a heavy load while bending over, or by direct forces to the sacrum, as in a fall from a great height. The patient complains of pain in the buttocks, perirectal area, and posterior thighs. There may be local pain, swelling, and bruising overlying the sacrum, and on gentle bimanual rectal examination, severe pain, abnormal motion, and palpable hematoma may be elicited. Radiographically the fracture may be difficult to visualize on anteroposterior (AP) and lateral projections, in which case an outlet view may be helpful. Simple transverse fractures at or below S4 are treated conservatively. Above S4, neurologic injuries are common, necessitating careful clinical evaluation and surgery when neurologic compromise is present.

Avulsion Fractures. These usually occur during athletic activities and are the result of a sudden, forceful muscular contraction or excessive muscle stretch. They are seen more commonly in older children and teenagers before closure of the corre-
sponding physis occurs; adults may have the same symptoms from ligamentous injury at these sites without radiographic abnormality.

The ischial tuberosity may be avulsed during strenuous contraction of the hamstrings. There is pain on palpation of the involved tuberosity, and this pain is increased by flexion of the hip with the knee in extension (hamstrings stretched), but not with the knee flexed (hamstrings relaxed). Ischial tuberosity avulsion also may cause chronic discomfort with no history of acute injury.

A portion of the iliac crest epiphysis may be avulsed by contraction of the abdominal muscles. Similarly, the anterior superior iliac spine may be avulsed by forcible contraction of the sartorius muscle. Forceful contraction of the rectus femoris (as in kicking a ball) can result in the less common injury of anterior inferior iliac spine avulsion; however, this radiographic finding must be distinguished from a normal variant, the os acetabuli, which is a secondary center of ossification at the superolateral margin of the acetabulum. Clinical examination is similar in these injuries and reveals local pain, swelling, and limitation of motion.

Conservative treatment, including analgesia and bedrest in a position that avoids tension on the affected muscles, is generally all that is required for avulsion injuries; surgical treatment is rarely necessary. Orthopedic consultation is advised for follow-up care.

**Stress Fractures.** These injuries occur with vigorous athletic or military training and in the last trimester of pregnancy. Diagnosis of stress fractures is based on the clinical evaluation and can be confirmed by radionuclide bone scan, although magnetic resonance imaging has been shown to be a superior method for detecting these injuries.

**Pathologic and Insufficiency Fractures.** Pathologic fracture related to neoplasia, Paget’s disease, or dietary osteomalacia is included in the differential diagnosis. Radiation therapy has also been shown to increase the risk of pelvic fracture.

### Partially Stable and Unstable Injuries (Tile Types B and C)

These injuries are caused by high-energy impacts. The forces applied to the pelvis determine the types of injuries that occur. Broadly, forces may be applied to the pelvic ring in AP, lateral, or vertical directions that result in characteristic injury patterns; combinations of forces result in more complex injuries.

The terms *unstable fracture* (referring to mechanical stability) and *unstable patient* (referring to hemodynamic status) should not be confused, although a cause-and-effect relationship often exists.

**Anteroposterior Compression.** Severe AP compression forces result in disruption at or near the symphysis pubis. Symphysis widening of less than 2.5 cm is considered a stable injury; however, with continued force in the AP direction, the hemipelvis externally rotates, tearing the sacrospinous, sacrotuberous, and anterior SI ligaments. The SI joint opens and hinges on the intact posterior SI ligaments. The resulting injury is aptly described as an “open-book” fracture. The pelvis is rotationally unstable in the horizontal plane, but the intact posterior SI ligaments maintain vertical stability.

When diastasis of the pubic symphysis is greater than 2.5 cm on the AP radiograph, the posterior injury is usually seen as widening of the SI joint and occasionally as a sacral or iliac fracture (Fig. 52-6). If the injurious forces continue, they may separate the hemipelvis, and the SI joint is seen as widely separated on the plain AP radiograph (Fig. 52-7) and the CT scan. The AP radiograph may be misleading in suggesting a pure open-book fracture in cases with symphysis disruptions greater than 2.5 cm. These cases commonly are associated with vertical shear fractures, and careful clinical and CT assessment for vertical instability is essential to classify the fracture properly and plan treatment.

These same forces also may injure the neurologic and vascular structures at the posterior arch; the overall volume of the pelvis is increased in the open-book injury, facilitating the expansion of a retroperitoneal hematoma. In several studies of patients with major pelvic ring disruptions, patients with severe grades of AP compression injuries have the highest crystalloid and blood requirements.

**Lateral Compression.** Lateral compression of the pelvic ring results in varying degrees of internal rotation of the affected hemipelvis. Initially, this causes buckling of the sacrum and horizontal pubic rami fractures. Rami fractures may occur on the ipsilateral or contralateral side, the latter being referred to as the “bucket-handle” fracture (Fig. 52-8).

As the magnitude of force increases, the symphysis may disrupt, causing overlapping of the pubic bones. Note that on plain radiographs, evidence of injury to the sacrum may be subtle; overlapping pubic bones with any significant displacement should prompt a search for a posterior injury.

Similar to the AP injury, with increasing disruption of the posterior ligaments comes increasing rotational instability. In the most severe lateral compression trauma, the ipsilateral pelvis internally rotates to such a degree that the contralateral pelvis may externally rotate. This is referred to as the “wind-swept” pelvis. Although lateral compressive injuries may result in varying degrees of rotational instability, the vertical stability of the pelvis is maintained (see Fig. 52-6).

As internal rotation causes the pelvic volume to decrease, lateral compressive injuries are generally associated with lesser degrees of blood loss than are AP injuries.

**Vertical Shear.** Vertical shear injuries represent the most unstable injuries to the pelvic ring and are associated with violent axial loading of the hemipelvis (e.g., fall from height, “submarining” underneath a dashboard). Fractures occur in vertical planes. Anteriorly, the symphysis and rami may be disrupted. Posteriorly, gross displacement and instability in the rotational and vertical planes may be present through the sacrum, the SI joint, or the ilium such that the hemipelvis may displace posteriorly and/or cephalad (sites of insertion of ligaments) (Fig. 52-9 and Box 52-3) are important clues to the presence of vertical shear fractures.

The vertical shearing forces that act on the bone also act on the rich vascular network and nerve plexus that are directly adjacent to the bone. This activity accounts for the major hemorrhage and neurologic injuries associated with vertical shear fractures.

**Vertical Sacral Fractures.** A crucial distinction in considering sacral fractures is that transverse fractures do not involve the pelvic ring, but vertical fractures do. Vertical sacral fractures are caused by high-energy injuries and are classified into three groups according to whether the fracture line extends (1) laterally to the sacral foramina, (2) through the foramina, or (3) medially to the foramina involving the central spinal canal. The diagnosis of this fracture on radiographs hinges on careful examination of the symmetrical cortical lines that are normally present at the superior margins of the sacral foramina on the AP view. Disruption, distortion, or asymmetry of these lines is an important marker of sacral fractures.

There is a high risk of neurologic complications associated with these injuries: 6% when lateral to the foramina, 28% when through the foramina, and 58% when medial to the foramina. Surgery is commonly necessary for fractures associated with neurologic dysfunction.
Figure 52-6. Young-Burgess classification. A, Lateral compression. Type I: A posteriorly directed force causing a sacral crushing injury and horizontal pubic ramus fractures ipsilaterally. Type II: A more anteriorly directed force causing horizontal pubic ramus fractures with an anterior sacral crushing injury and either disruption of the posterior sacroiliac joints or fractures through the iliac wing. Type III: An anteriorly directed force that is continued, causing external rotation of the contralateral side; the sacroiliac joint is opened posteriorly, and the sacrotuberous and spinous ligaments are disrupted. B, Anteroposterior (AP) compression. Type I: Symphysis disrupted but with intact posterior ligamentous structures. Type II: Continuation of a type I fracture with disruption of the sacrospinous and potentially the sacrotuberous ligaments and an anterior sacroiliac joint opening. Type III: Continuation force disrupts the sacroiliac ligaments. C, Vertical shear. Vertical fractures in the rami and disruption of all posterior ligaments. This injury is equivalent to an AP type III or a completely unstable and rotationally unstable fracture. Arrow indicates the direction of force. Open Pelvic Fractures

An open pelvic fracture is present when there is direct communication between the fracture site and a skin, rectal, or vaginal wound. These are potentially lethal injuries, especially if the open nature is not recognized: hemorrhage accounts for early mortality, but sepsis is the major cause of delayed death. The majority of case series prior to 1991 reported mortality rates greater than 50%; reported rates between 1991 and 1999 ranged between 5 and 30%, although a recent series reported a 45% mortality rate.

The skin over the posterior pelvis and gluteal area and perineum must be inspected carefully for wounds. Some fractures are open only by virtue of a bone spicule penetrating the vagina or rectum, but these must be identified by careful digital rectal and vaginal examinations. Hemorrhage from a large open laceration should be treated by direct manual pressure or pressure dressing. Pelvic fractures communicating with the rectum have traditionally mandated a diverting colostomy; however, a systematic review of the literature on this topic found no difference in infection rates between patients treated with colostomy and those treated without.

Penetrating Pelvic Trauma

Because of the complex anatomy of the viscera, blood vessels, and nerves within the pelvis, penetrating trauma to this area presents a major challenge to the physician. Overall mortality in this group of patients has been reported to be 6 to 12%, but the mortality rate of patients in shock is 50%. At surgery, vascular injuries singly and in combination were found to involve the aorta; common iliac artery; and external, internal, and common iliac veins. Injuries to genitourinary structures and hollow viscera were common, and a particular concern was fecal contamination from colorectal injury. When present, the finding of blood on digital rectal examination is an important clue that rectal injury has occurred. Emergent surgical consultation is required in all cases of penetrating pelvic trauma.

CLINICAL FEATURES

History

Understanding the mechanism of injury is an important means of determining a patient’s risk of having a pelvic fracture and the severity of the fracture when present. Low-energy injuries (e.g., fall on level ground) typically cause stable injuries to the pelvis; patients who have sustained high-energy injuries (e.g., MVCs, falls from heights) are at risk for unstable fracture patterns of the pelvis as well as associated injuries to other organ systems.

Determining the direction of forces applied to the pelvis can also give important clues to the types of injury sustained.
Injury or cephalad migration of an unstable hemipelvis. Careful inspection of the skin and skin folds is necessary to identify open fractures. Perineal ecchymosis or hematoma may be observed, and in cases when many hours have elapsed since the injury, ecchymosis in the periumbilical area (Cullen’s sign) or flanks (Grey Turner’s sign) from retroperitoneal hemorrhage may be present. The presence of point tenderness on palpation anywhere on the pelvic ring from the symphysis anteriorly to the sacrum and SI joints posteriorly is an indicator of pelvic ring injury in alert patients without distracting injury.27

Manipulation of the pelvis must be kept to a minimum. “Spring boarding” of the pelvis to assess stability of the pelvic ring should be strictly avoided as this maneuver has the potential to disrupt any tenuous blood clotting that may have occurred around a fracture site and may therefore worsen hemorrhage.

The penis should be milked to examine for blood at the meatus. The digital rectal examination should evaluate sensation, sphincter tone, position and consistency of the prostate, presence of a presacral hematoma, bony contour of the sacrum and coccyx, mucosal penetration of bony spicules, and presence of frank or occult blood. In the setting of a pelvic fracture, female patients should undergo a vaginal examination to diagnose an open fracture. Because it is possible to create an open fracture iatrogenically through the vaginal or rectal wall, digital rectal and vaginal examinations should be performed carefully, especially in an unconscious patient who cannot localize pain. The examiner should be mindful when performing these examinations that bony spicules can cause him- or herself injury. Extravasated urine may be detected in the scrotum or the subcutaneous tissues of the penis, vulva, or abdominal wall. The presence and quality of pulses in the lower limb should be assessed, as should sensation, strength, and deep tendon reflexes.

**Associated Pelvic Injuries**

**Urologic**

The overall incidence of bladder or urethral disruption associated with any pelvic fracture is approximately 6%2 with increased risk among those with severe pelvic injuries.3 Urethral rupture in women with pelvic fractures has been reported but is exceedingly rare.29

A review of 721 patients with pelvic fracture revealed an incidence of bladder rupture in 5% of patients. Those with fractures of the anterior arch of the pelvis are at greatest risk for bladder injury: diastasis of the symphysis more than 1 cm and fracture around the obturator ring with displacement greater than 1 cm were associated with a 10- and 3-fold increased risk of bladder rupture, respectively.30

The presence of gross hematuria mandates evaluation of the lower urinary tract. Blood at the urethral meatus necessitates a retrograde urethrogram followed by a cystogram. Gross hematuria is investigated by a combination of urethrography, intravenous pyelography, cystography, and CT. The sequence and types of examinations are individualized for each patient.

Sexual dysfunction in both men and women is a recognized complication of pelvic trauma. The incidence of impotence associated with urethral rupture is significant. In the absence of urethral injury, impotence still may occur secondary to neurovascular disruption associated with the pelvic fracture.31

**Physical Examination**

On inspection, rotation of the iliac crests indicates a serious pelvic fracture. Leg length discrepancy may suggest a hip

Anterior-posterior forces (e.g., head on MVCs) may cause open-book injuries to the pelvis. Lateral forces to the pelvis (e.g., side impact collisions) may disrupt the posterior ligaments; however, the pelvic floor generally remains intact. Vertical shear injuries (e.g., falls from height) may disrupt the posterior ligaments and pelvic floor causing gross instability of pelvis.

Age is an important consideration in patients with pelvic fracture. Studies consistently demonstrate higher morbidity and mortality among older patients with pelvic fracture.26 Osteopenic bone may be disrupted by lesser forces. Decreased physiologic reserves in older patients may limit success in the acute resuscitation and definitive treatment of injuries.

Injuries to other organ systems are extremely common in patients with pelvic fracture.24,25 It is important to identify all major injuries to other organ systems in order to prioritize definitive surgical treatment for the multiply traumatized patient. In women, it is important to consider the possibility of pregnancy and to test for pregnancy whenever appropriate.

**Neurologic**

Neurologic injury occurs commonly in patients with vertical sacral fractures or transverse fractures above the S4 level.
Among patients with vertical fractures that involve the foramina, 28% have associated neurologic deficits. In patients with fractures medial to the foramina involving the spinal canal, 56% have neurologic deficits.

Cauda equina syndrome and various plexopathies and radiculopathies may occur as follows. Injury to the L5 root may cause weakness of muscles in the anterior tibial compartment and sensory deficits in the dorsum of the foot and lateral calf. Injury to S1 and S2 roots may cause weakness of hip extension, knee flexion, and plantar flexion and sensory deficits on the posterior aspect of the leg, sole and lateral foot, and genitalia. Injury to S2-S5 roots and distal afferent, efferent, and autonomic fibers causes sensory deficits in the perineum, sexual dysfunction, and bowel and bladder dysfunction. Cauda equina syndrome may be fully or partially present with sacral fractures: Hyperesthesia and later anesthesia occur in a saddle-shaped distribution in the groin; in addition, weakness of ankle plantar flexion, hamstrings, and gluteus muscles and decreased or absent ankle jerk are present. With involvement of the lower sacral roots, a neurogenic bladder with overflow incontinence, motor and sensory deficits in the lower extremities, anal sphincter dysfunction, and sexual dysfunction may occur. All patients with neurologic deficits from sacral fractures require orthopedic or neurosurgical consultation.

Gynecologic

Blood at the introitus may indicate a urethral injury, open pelvic fracture, or local laceration without communication with the bony pelvis. Delayed urologic and sexual dysfunction and complications with pregnancy are common following pelvic injury. Gynecologic consultation is indicated when there is injury to the female reproductive tract in association with a pelvic fracture.

Associated Nonpelvic Injuries

The magnitude of force required to disrupt the pelvis commonly results in severe injuries to other organ systems. Among those patients who die with pelvic fracture, it is rare that the pelvic fracture is an isolated injury.

Some authors have described patterns of associated nonpelvic injuries with certain patterns of pelvic fracture; however, this has not been consistently reproduced in the literature. Severe injuries to head, spine, thorax, and abdomen may occur with both stable and unstable pelvic fractures; they may all occur with all major mechanisms of pelvic injury. One associated injury that reflects the dispersion of enormous forces throughout the body is the rupture of the thoracic aorta: albeit...
uncommon in blunt trauma, it is five to eight times more likely in patients with pelvic fracture.2,36

**DIAGNOSTIC STRATEGY**

**Radiology**

**Plain Radiography**

Routine radiographs of the pelvis are not necessary in cases of blunt trauma if the patient is asymptomatic, awake, and alert and has a normal physical examination of the pelvis.37-39 However, routine AP plain radiograph of the pelvis (PXR) is advised by the Advanced Trauma Life Support (ATLS) guidelines for patients with severe mechanisms of injury who are symptomatic or whose examination is compromised by either decreased level of consciousness or distracting injuries.

On the AP radiograph, the symphysis pubis is normally no more than 5 mm wide, and a small (1- or 2-mm) vertical offset of the left and right pubic rami is normal.39 Overlapping at the symphysis pubis is abnormal and is the result of a severe crushing injury. Normally the SI joint is approximately 2 to 4 mm wide.16

On the AP view, the physician may judge the degree of pelvic rotation caused by technique and positioning by the presence of asymmetry in the size and shape of the left and right obturator foramina and iliac wings. Diastasis of the SI joint also causes an asymmetrical appearance of the obturator foramina and the iliac wings: If there is displacement into external rotation, the affected iliac wing appears broader, and the anterior iliac spine appears more prominent.16 Avulsion fracture of the fifth lumbar transverse process by the iliolumbar ligament often accompanies an SI joint disruption or a vertical sacral fracture and is a valuable clue to posterior arch injuries16 (see Fig. 52-9; Box 52-3).16

Recently, the reliability of the single AP PXR to detect pelvic fractures has been questioned. Two case series have

---

**Figure 52-9.** A and B, Vertical shear fractures bilaterally. At first glance, the pelvis appears normal because of the smooth, uninterrupted arcuate line, but careful interpretation reveals the extremely critical nature of the injuries: (1) Fractures through the sacrum—note loss of definition and symmetry of sacral foramina, indicating vertical fractures through both sides of the sacrum (see computed tomography scan in D). (2) Transverse process fragment from right L5 (iliolumbar ligament attachment) is pathognomonic for a vertical shear fracture through the right sacrum. (3) Transverse process fragment from left L5, pathognomonic for a vertical shear fracture through the left sacrum. (4) Both hemipelves are dislocated cephalad because of the double-ring fractures through each side of the sacrum. This dislocation explains why the L5 transverse processes appear so close to the iliac crests (the body of L5 is obscured because of rotational dislocation of the central free sacral fragment posteriorly and because of technique). (5) Normal sacroiliac joints. C and D, Computed tomography scan of same pelvis. (1) Bilateral comminuted fractures of sacrum with lateral displacement of both hemipelves, (2) normal sacroiliac joints.
reported sensitivities of only 64 and 68% with specificities of 90 and 98%, respectively, thus prompting a question of the utility for PXR when patients are to undergo immediate abdominopelvic CT evaluation. In particular, sacral fractures and SI joint disruptions may not be well visualized on the AP view. However, the addition of inlet and outlet views of the pelvis has been shown to increase the sensitivity and specificity of plain radiographs in detecting significant pelvic fracture (Fig. 52-10) and SI joint disruption and should be considered in all patients with presumed stable anterior pelvic ring injuries with any complaints of posterior pelvic pain.

When patients are too unstable to undergo CT investigation, the AP PXR is useful in screening for pelvic injuries that are most associated with major blood loss. Findings on AP PXR that have been reported to predict the need for transfusion include open-book fracture or displacement of 0.5 cm or more at any fracture site in the pelvic ring and displaced symphysis pubis or displaced obturator ring fracture. It is important to note that all of these signs may be associated with posterior pelvic injury. As such, the PXR is a vital test in the absence of CT and should be used to alert both surgeons and angiographers to the potential need for definitive management of pelvic hemorrhage.

Computed Tomography
CT has become the imaging test of choice for evaluating the injured pelvis. CT provides detailed information about the posterior arch and rotational deformities that indicate the relative stability of the pelvic ring; furthermore, the acetabulum, which may be difficult to assess with plain radiographs, can be well visualized using CT. CT has demonstrated a much higher sensitivity and specificity over plain radiography in detecting pelvic fracture. Furthermore, abdominopelvic CT provides detailed information about concomitant injury to abdominal organs that aids in the planning of laparotomy, external fixa-

Figure 52-10. A, The inlet and outlet views. The inlet view is angled 60 degrees to the plate from head to feet; the outlet view is angled 30 degrees in the opposite direction. Both views can be obtained with a portable machine if necessary. Injuries to the sacrum and sacroiliac joint are commonly difficult to visualize with the anteroposterior view only. The combination of all three views allows the identification of virtually all significant injuries to the bony pelvis. B, Inlet of pelvis is well demonstrated in this radiograph of a unilateral vertical shear fracture with cephalad and posterior displacement of the left hemipelvis. C, Schematic of unilateral vertical shear fracture. (1) Normal sacral ala on the right side, (2) left sacral ala is indistinct because of a vertical fracture, and the cephalad and posterior displacement of this hemipelvis is shown by this inlet projection, (3) ischial spine on the left is partially obscured by bowel gas, but it is located more cephalad compared with the right spine because of cephalad displacement of the left hemipelvis, (4) fractured left superior pubic ramus with displacement cephalad, (5) the inlet view is taken looking through the superior and inferior pubic rami, which are superimposed so that the obturator foramina are not seen.
Evaluation of Hemorrhage

Hemorrhage is the most devastating direct complication of pelvic fracture. In the original series of high-energy pelvic injuries used to formulate their classification system, Burgess and colleagues’ analysis of blood transfusions required an average of 14.8 U in the AP compression group, 9.2 U in the vertical shear group, and 3.6 U in the lateral compression group. The finding has been confirmed in more recent studies that demonstrate that unstable fracture patterns increase the need for transfusion and risk of mortality, with one series reporting median of 10 U of blood required (range 1–70 U).3

Bleeding results from lacerations of the rich vascular network supplying the pelvis and collects in the retroperitoneal space, but bleeding also may occur from the narrow at the fracture sites. Coagulopathy is another cause of persistent retroperitoneal bleeding and should be considered when the patient does not respond to fluid and blood replacement.

Pelvic hemorrhage is commonly venous in origin and may be contained and tamponaded retroperitoneally by an intact peritoneum. However, it is possible for bleeding to extend beyond the retroperitoneum and dissect into the anterior abdominal wall (to the chargin of the unwise clinician who introduces a scalpel or peritoneal dialysis catheter) or through the peritoneum into the abdominal cavity.

The combination of both pelvic and intra-abdominal bleeding is associated with devastating outcomes. In one large series, major pelvic injury was associated with intra-abdominal injuries in 31%; the liver and spleen were injured in 10 and 6% of these cases, respectively.5 In the patient with pelvic fracture who presents in shock, it is important to establish early on whether there is hemorrhage within the abdominal cavity necessitating laparotomy. Diagnostic strategies for evaluation of pelvic fracture-associated hemorrhage include diagnostic peritoneal lavage (DPL), ultrasound, and CT. Regardless of the modality of evaluation, it is crucial to avoid unnecessary laparotomy because of the higher mortality rate for hemodynamically unstable patients with pelvic fractures who undergo a negative abdominal exploration.

Diagnostic Peritoneal Lavage

DPL is a widely accepted, rapid, and accurate means of establishing the presence of intra-abdominal hemorrhage. Although it has been largely supplanted in many centers by ultrasound and CT, DPL nevertheless remains an effective tool to assist with difficult triage decisions in the trauma patient. A pelvic fracture presents a special situation for DPL because of the possibility that a retroperitoneal hematoma may dissect into the anterior abdominal wall. However, when a fully open technique is used (i.e., the peritoneum is entered under direct visual control), the false-positive and false-negative rates are each 0.7%.47

The DPL may be performed in the infraumbilical location in most patients; however, the supraumbilical location should be employed if any of the following conditions are present: prior abdominal scars, time delay since the injury of more than 1 hour, or a hematoma encountered during the procedure.47

A negative peritoneal aspirate indicates that the peritoneal cavity is not a major source of bleeding or a significant contributor to hemorrhagic shock. Assuming that external and thoracic sources of blood loss have been eliminated as causes of hemodynamic instability, a negative peritoneal aspirate in a patient with a major pelvic fracture indicates pelvic hemorrhage. Angiography with rapid therapeutic embolization and mechanical fracture stabilization should be pursued.

Gross aspiration of blood indicates possible major intra-abdominal hemorrhage and laparotomy is recommended at the earliest opportunity for hemodynamically unstable patients.47 The lavage that is positive by cell count criteria alone is a special situation. If these patients are hemodynamically unstable, it is advisable to perform angiography with therapeutic embolization and external pelvis fixation before laparotomy.46,47

Ultrasound

Focused assessment with sonography for trauma (FAST) is widely used to identify free intraperitoneal fluid in the trauma patient. An important caveat to note is that FAST is not helpful for evaluating the retroperitoneal space where pelvic hemorrhage occurs. Although a positive FAST study that shows free fluid is widely used as a triage point to decide on laparotomy in a hemodynamically unstable patient, its reliability in patients with major pelvic injury has been questioned. Sensitivities ranging from 24 to 81% and specificities ranging from 87 to 96% for the detection of hemoperitoneum have been reported48,49 in patients with pelvic fracture.

Although these reports come from retrospective case series—and therefore do not necessarily represent the highest levels of evidence—the high incidence of false-negative FAST exams reported in the literature among patients with pelvic injury is nonetheless cause for concern. This is because pelvic and intra-abdominal hemorrhages are highly associated and, in combination, result in major blood loss.53

Computed Tomography

CT is unquestionably the diagnostic test of choice for detecting pelvic and intra-abdominal injuries. It reveals bleeding in both the peritoneal and retroperitoneal spaces. CT with intravenous contrast often can distinguish a stable hematoma from ongoing bleeding from pelvic arteries. The presence or absence of extravasated intravenous contrast material on CT scan of the pelvis is useful in predicting which patients will require therapeutic angiography; however, its absence does not rule out ongoing pelvic bleeding: One series found the sensitivity for the detection of arterial bleeding by CT to be only 66% in patients who also had angiography.51

MANAGEMENT

Resuscitation

The mortality rate in patients with blunt trauma who have the combination of pelvic ring fractures and hemorrhagic shock is approximately 50%. ATLS guidelines advocate the initial use of crystalloid solutions to stabilize vital signs in the trauma patient. However, when severe hypotension is present in patients with severe pelvic fracture, transfusion of blood products (including packed red blood cells, plasma, platelets, and occasionally cryoprecipitate) is crucial early in the resuscitation. Some patients appear to achieve hemodynamic stability after minimal volume infusion only to decompensate precipitously. It is important to note that case series commonly report patients with severe pelvic injury requiring transfusion of packed red blood cells in the order of 10 to 20 U within the first 24 to 48 hours.
The endpoint for fluid resuscitation should be evidence of end-organ perfusion. A large body of evidence from animal studies suggests that standard volumes of crystalloid fluids typically used in traumatic hemorrhagic shock to restore normal heart rate and blood pressure lead to greater volumes of blood loss compared with low-volume resuscitation strategies that accept lower systemic blood pressures. For patients with severe pelvic fracture, attempts to achieve normocardiacy and normotension with fluid resuscitation in the ED should not delay more definitive treatments to halt the hemorrhagic process.

Lower limb intravenous sites should be avoided in patients with severe pelvic fractures because the infused products may be delivered to the retroperitoneal space. Box 52-4 details the methods for controlling hemorrhage in the ED phase of the care of patients with pelvic fractures.

**Control of Hemorrhage**

In addition to blood transfusion, two important therapeutic modalities for control of hemorrhage are mechanical stabilization of the pelvis and angiographic embolization. There has been some debate as to which of these modalities should take precedence, and this has been predicated on institutional availability. As a general rule, angiography with therapeutic embolization of bleeding arteries is more effective than and takes precedence over external fixation.

**Stabilizing the Pelvis**

*Noninvasive Techniques.* The most readily available means to quickly stabilize the pelvis in the ED may be realized with a simple sheet and towel clamps. Wrapping the pelvis tightly with a sheet and securing this with towel clamps has been shown to be effective in reducing an open-book pelvic injury (Fig. 52-11), thereby reducing the potential volume in the pelvis for blood loss.

Other devices have been developed to facilitate noninvasive splinting of the pelvis. One retrospective comparison of patients with exsanguinating pelvic hemorrhage found that patients treated with a noninvasive splinting device had substantially lower transfusion requirements than those who had formal external fixation of their pelvis performed emergently (4.9 U vs. 17.1 U in the first 24 hours, *p* = 0.008). However, there was no statistically significant change in mortality between the two groups (26% vs. 37%, *p* = 0.11).

Patients who have sustained AP open-book injuries are likely to derive the most benefit from tight wrapping of the pelvis. This maneuver may not be desirable when lateral compression forces have already internally rotated the hemipelvis because indiscriminately forceful wrapping may, in fact,
worsen the degree of displacement. Here, some judgment is required to discern whether one is wrapping the pelvis to reduce the volume of an externally rotated pelvis versus splitting a pelvis that is internally rotated due to lateral compression in order to minimize pelvic movement that may occur, especially when transferring the patient.

**Invasive Fixation.** External fixation of the pelvis is always performed by orthopedic surgeons. The goal of fixation is to prevent movement at pelvic fracture sites and attendant bleeding.11 Although the acute application of an external fixator has not been proved to decrease morbidity or mortality in a prospective study, there is evidence that this technique improves clinical outcome by limiting hemorrhage and restoring mechanical integrity.46 Application of the fixator is time-consuming; therefore, it should not delay more definitive treatment of pelvic bleeding by angiography or the treatment of other sources of severe blood loss. The timing of the application of the external fixator requires coordination between the trauma surgeon and orthopedic surgeon. Early surgical consultation is vital to efficient planning and prioritization of surgical management.

Many stable AP and lateral compression fractures can be treated definitively by the external fixator.11 When the pelvis is vertically displaced, traction combined with external fixation is necessary to reduce the pelvis while waiting for definitive open surgical repair.11 Most fixators can be constructed to allow convenient surgical access to the abdomen and groin.

The pelvic C-clamp can theoretically be applied rapidly by the orthopedic surgeon in the ED to externally stabilize the posterior pelvic arch on an emergency basis.60,64 It is likely more effective in reducing AP than vertical injuries.62 Institutional practices may influence the use of C-clamp over standard external fixation. Although the C-clamp may aid in stabilizing blood loss, its application does not obviate the need for angiography.65 It is unclear whether the C-clamp offers any additional advantage over wrapping the pelvis with a sheet during initial resuscitation efforts.

**Angiography and Embolization.**

Arteriography and venography have been investigated for managing hemorrhage associated with pelvic fractures. Although pelvic bleeding is commonly venous in origin, venography is not useful in managing these cases: the extensive anastomoses and valveless collateral flow make embolization ineffective. In contrast, arteriography is excellent at both diagnosing and managing arterial bleeding.

The arteriogram is performed with the contrast material injected through the femoral artery on the least-injured side or via the upper extremity. The examination starts above the level of the aortic bifurcation and proceeds to selective branches of the internal iliac (hypogastric) artery.64 Transcatheter embolization using thrombogenic coils, foam, or spherules is employed to stop the hemorrhage from the branches of the internal iliac artery.

Embolization is highly effective for controlling arterial bleeding. One case series of 556 patients undergoing pelvic angiography reported that repeat angiography was necessary in only 7.5% of patients due to ongoing bleeding. These authors found that hypotension, a need for more than 2 U of packed red cells, symphysis widening, and more than two arteries embolized at the first angiogram predicted the need for repeat angiography.65

Angiography is indicated when hypovolemia persists in a patient with a major pelvic fracture, despite control of hemorrhage from other sources. Although it is impossible to determine whether bleeding is venous or arterial in origin until angiography is performed, one study found that inadequate response to initial resuscitation (defined as failure to maintain a systolic blood pressure above 90 mm Hg after the administration of 2 U of packed red cells, or less) and the presence of contrast extravasation on admission CT were both indicative of active arterial bleeding.65 Although the presence of contrast extravasation on CT is an indication for angiography, the absence of contrast blush on CT is not sufficient to rule out serious pelvic bleeding.55,66

The timing of angiography is individualized for each patient depending on priorities for treatment of concomitant injuries. Posterior arch disruptions are associated with the most severe hemorrhage; angiography should be considered at an early stage for these patients. Whether patients undergo angiography immediately from the ED or angiography immediately precedes laparotomy, it is important to be mindful of the logistical delay that often occurs in mobilizing the angiography team, so this intervention should be anticipated as early as possible. The transfer of the patient to the angiography suite also requires orchestrating the necessary personnel and equipment to care for the critically injured patient there.

**Hemodynamically Unstable Patients with Pelvic and Intra-abdominal Hemorrhage.**

Patients who hemorrhage from both the pelvis and abdomen have mortality rates above 40% and deserve special consideration. These patients may be too unstable to undergo CT imaging. Prioritizing the need for laparotomy versus angiography in these patients may be challenging when the need for laparotomy is based on the detection of intra-abdominal fluid by FAST or DPL. In these cases, it is crucial that the efforts of the general surgeon, orthopedic surgeon, and interventional radiologist be coordinated to optimize the timing of necessary procedures.

Gross aspirates of blood on DPL are strong indicators for prompt laparotomy. Given the high rates of false-negative FAST exams in pelvic trauma, caution must be used when making difficult triage decisions regarding laparotomy versus angiography on the basis of FAST findings in this setting. However, when the FAST exam does reveal hemoperitoneum, it is generally accepted that laparotomy be pursued first.57 When concurrent pelvic bleeding is highly suggested (e.g., severe open-book pelvis), it is advisable that angiography promptly follow laparotomy.

It may be appropriate for the orthopedic surgeon to place either an external fixator or pelvic C-clamp at the time of laparotomy. Packing of the pelvis at the time of laparotomy has been reported as a means to obtain hemostasis in pelvic hemorrhage.66,69 Although there is limited evidence from clinical studies to support packing, it is regularly used at some centers, especially in Europe. Part of the rationale for employing packing rather than angiography is the fact that pelvic bleeding is commonly venous in origin, for which arteriography is useless. In contrast, packing may aid in tamponading bleeding from the posterior venous plexus. It is recommended that the pelvis be stabilized prior to packing to provide solid structural support against which packing may be performed.59

When FAST or DPL do not reveal hemoperitoneum in the presence of severe pelvic fracture, emergent angiography should be arranged. If pelvic bleeding continues despite angiography (i.e., secondary to venous bleeding), open stabilization and packing should be considered as the next step.

For any trauma center, planning for challenging clinical situations among trauma surgeons and angiographers and the creation of protocols for care may be useful in optimizing a timely and coordinated response.56
Acetabular Fractures

Many pelvic fractures in adults involve the acetabulum. Pain and inability to bear weight are the hallmark complaints associated with acetabular fractures. On clinical exam, pain on percussion of the sole of the foot or the greater trochanter may reproduce pain. It is important to note the presence of neurologic deficit as the sciatic nerve is commonly injured. Fracture or dislocation of the patella (or both) are also common. Acetabular fractures are broadly classified into three types (Fig. 52-12, Box 52-5).

Type A fractures may be subdivided into anterior and posterior column injuries. Posterior wall fractures are the most common acetabular injuries and are generally caused by a forceful impact to a flexed knee (e.g., dashboard injury)—the force is transmitted up through the femur through the posterior acetabulum. An associated posterior dislocation of the hip is frequently associated with posterior rim fracture of the acetabulum and may result in an unstable hip joint and recurrent dislocation. Posterior hip dislocation is commonly associated with secondary sciatic nerve injury. The anterior column of the acetabulum is commonly injured when a superior ramus fracture extends into the low anterior column.

Type B fractures involve both anterior and posterior columns, but a portion of the acetabulum remains attached to the ilium. When the columns are split, this is referred to as a T fracture. The T fracture is associated with the worst prognosis, owing to the difficulty in obtaining open anatomic reduction.

Type C fractures are readily apparent on plain radiographs as a result of disruption of the ilium.

Assessment of the AP pelvic radiograph should focus on the disruption of the ilioischial and ilipectineal lines as well as the anterior and posterior lips of the acetabulum (Fig. 52-13). Ramus fractures should be evaluated for possible extension into the acetabulum. Oblique views of the acetabulum (Judet’s views) can aid in visualizing the anterior and posterior columns. CT is, without question, the imaging test of choice for visualizing acetabular fractures and planning for possible surgical repair. All patients with acetabular fracture require orthopedic referral in the emergency department.

Coccyx Fractures

Fractures of the coccyx occur frequently after a fall in the sitting position or a kick. Fracture and injury also may occur during parturition. Physical examination reveals local tenderness to palpation in the gluteal crease, with pain and, sometimes, abnormal motion of the coccyx during palpation on digital rectal examination. Normally the tip of the coccyx moves 30 degrees anteriorly and 1 cm laterally. Displacement also is diagnosed on rectal examination, but attempts at reduction are not recommended.

Radiographic confirmation of a coccygeal fracture is not always necessary. Displaced fractures often are seen on the lateral view, but the diagnosis is evident on rectal examination.
Undisplaced fractures may be difficult to show radiographically. The physician must decide whether the knowledge gleaned from radiographic studies would alter the therapy to a degree that warrants radiation exposure to the pelvis, especially considering that most of these fractures occur in women.

Treatment of coccygeal fracture consists of bedrest, stool softeners, analgesia, and sitz baths to relieve muscle spasm. As activity is increased, maneuvers that may minimize discomfort include using an inflatable rubber donut cushion, alternate sitting on the side of each buttock, slouching to displace body weight more proximally, and sitting on a hard chair rather than a soft one (sinking into a soft chair may distribute weight onto the coccyx). Because of muscle action on the fragment, healing is slow and patients must be cautioned that discomfort may be prolonged. In the case of persistent severe disability, an orthopedic consultation is indicated for considerations of local steroid injection or possible coccygectomy. Other causes of coccydynia (besides fracture) include trauma during parturition; faulty posture; midline disk herniations (caused by non-segmental referral of pain from irritation of the dura); lumbar facet arthropathy; compression of the first, fourth, and fifth sacral roots; neuralgia from sacral plexopathy or sacrococcygeal neuropathy; infections; and local tumors.

**KEY CONCEPTS**

- The most serious pelvic ring injuries caused by high-energy impact include (1) AP compression fractures (open book), (2) vertical shear fractures, and (3) any fractures that involve significant displacement. These are associated with major blood loss and transfusion requirements.
- Pelvic injury is a marker for serious injury to other organ systems. The vast majority of patients who die with pelvic fracture are those who have sustained multiple trauma.
- Careful examination of the skin in the perineum and buttocks and digital rectal and vaginal examinations are necessary to diagnose open fractures because these are associated with the highest mortality rates.
- CT is the imaging test of choice to diagnose pelvic fracture and concurrent intra-abdominal injuries for patients stable enough to undergo CT. CT aids in establishing surgical priorities and planning of definitive orthopedic care.
- In the hemodynamically unstable patient who cannot undergo CT imaging, the AP radiograph usually reveals those pelvic fractures most closely associated with major pelvic bleeding. Inlet and outlet radiographs improve the sensitivity and specificity of pelvic plain radiography.
- Trauma hospitals should have institutional guidelines and mechanisms to access angiography and external fixation.
- The combination of posterior arch fracture plus hypotension is associated with a mortality rate of approximately 50%. Early resuscitation with blood products is recommended. Decisions regarding the need for angiographic transcatheter embolization and external pelvic fixation must be made early in the course of care.

Background

Ancient Egyptian and Greek drawings depict a lame person afflicted with hip deformities ambulating with a cane. The first available written description of a hip fracture was by the 16th-century French surgeon Ambroise Paré. In 1850, Von Langenbeck was the first to attempt repair of a hip fracture with a nail for internal fixation. Later, Davis used ordinary wood screws in an attempt to aid the healing of femoral neck fractures. With the advent of radiography in the 19th century, the types of fractures and dislocations became easily identifiable, thus allowing discussion and investigation of management strategies, classification systems, and prognosis.

Epidemiology

Both age and gender are important predisposing factors for specific injury patterns seen in and pathologic conditions affecting the hip, femur, and thigh.

As a whole, the elderly segment of society almost universally suffers from some type of hip pathology. Osteoarthritis of the hip can severely limit the affected person’s ability to perform activities of daily living. Approximately 6 million women in the United States suffer from osteoporosis, and an additional 17 million have osteopenia, both of which predispose to hip fracture. During the late 1990s, approximately 250,000 patients a year sought treatment in emergency departments (EDs) after sustaining a hip fracture. As baby boomers mature, the number of hip fractures is expected to reach half a million a year by 2050. Eighty percent of femoral neck fractures occur in men. The average age of patients who sustain femoral neck fractures is 72 years for men and 77 years for women. On average, intertrochanteric fractures occur 10 to 12 years later than those of the femoral neck, and women are afflicted eight times more often than men. Overall, three quarters of all hip fractures occur in postmenopausal women older than 50 years.

Pertes’ disease—avascular necrosis (AVN) of the femoral head—is four times more common in boys than in girls and occurs between 3 and 12 years of age. Slipped capital femoral epiphysis (SCFE) is twice as common in boys and peaks at 13 years of age among boys and 11 years among girls, in association with the onset of puberty.

Anatomy of the Hip and Femur

Skeletal Anatomy

The femoral head is firmly seated in the acetabulum, which is reinforced by labral cartilage. The well-developed capsule, overlying ligaments, and proximal musculature of the lower extremity add strength to the joint (Fig. 53-1). The nearly spherical femoral head articulates with the acetabular cup in a variation of the ball-and-socket joint. The femur is the longest and strongest bone in the human body and is routinely subjected to substantial forces produced during powerful muscle contraction and weight transmission. In an anatomic position, the two femurs extend obliquely from the pelvis medially to the knee and bring the legs closer to the midline, where they can best support the body. Structurally, the femoral neck serves as an oblique strut between the pelvis (the horizontal beam) and the shaft of the femur (the vertical beam) (Fig. 53-2). The length, angle, and narrow circumference of the femoral neck permit substantial range of motion at the hip, but these same characteristics subject the neck to incredible shearing forces. A fracture results when these forces exceed the strength of the bone. As drawn on an anteroposterior radiograph, the intertrochanteric line, an oblique line connecting the greater and lesser trochanters, marks the junction of the femoral neck and its shaft.

The bone in the femoral head, neck, and intertrochanteric region is predominantly cancellous, which is less resistant to torsional forces. Distal to the intertrochanteric region, including both the subtrochanteric region and femoral shaft, the bone is cortical, requiring great forces to break. At the distal metaphysis, the femur widens and the cortical bone thins, lessening its resistance to stress.

Musculature

The musculature of the hip and thigh is the largest and most powerful in the human body. The muscles in this region of the body are located within three different compartments, each containing associated nerves and vessels (Table 53-1). The muscles also are grouped according to their primary action at the hip. Knowledge of the major muscle actions offers
insight into the injury patterns and deformities commonly seen (Fig. 53-3).

**Vascular Anatomy**

**Arterial Supply**

The arterial supply to the femoral head arises from three sources (Fig. 53-4). The major source is the ascending cervical arteries as they branch off the extracapsular ring and run along the femoral neck beneath the synovium. Some blood is supplied to the femoral head from the second source, within the marrow spaces—the intraosseous cervical vessels. A third and dubious source is the foveal artery as it lies within the ligamentum teres.

As the external iliac artery passes beneath the inguinal ligament, it becomes the common femoral artery. At this point the artery is located midway between the anterior superior iliac spine and the symphysis pubis. Approximately 3 to 4 cm distal to the inguinal ligament, the common femoral artery branches to form the superficial and deep femoral arteries. The larger superficial femoral artery passes along the anteromedial aspect of the thigh and terminates at the junction of the middle and lower thirds of the thigh. Here, the superficial femoral artery passes through the adductor hiatus and becomes the popliteal artery. The deep femoral artery runs posterolateral to the superficial femoral artery, supplies the hamstrings, and terminates in the distal third of the thigh as small branches piercing the belly of the adductor magnus. These perforating branches constitute an additional site of potential injury. The abundant blood supply of the thigh aids in healing fractures of the femoral shaft.

**Venous System**

In the proximal two thirds of the thigh, the common and superficial femoral veins lie adjacent to the common and superficial femoral arteries. The veins remain patent during hemorrhage and can be utilized for blood transfusion. The veins are supplied by the inferior epigastric and superior gluteal veins.

superficial femoral arteries. At the inguinal ligament, the common femoral vein is posterior and medial to the common femoral artery and moves to the lateral position as it passes distally. The deep femoral vein and the greater saphenous vein are the two main tributaries to the common and superficial femoral veins. The deep femoral vein and artery run parallel as the vein joins the superficial femoral vein just distal to the inguinal ligament. The greater saphenous vein arises in the dorsum of the foot and ascends anterior to the medial malleolus. This vein is relatively superficial as it passes up the medial aspect of the leg to join the common femoral vein distal to the inguinal ligament.8

Nerves

The femoral and sciatic nerves are the major nerves within the thigh. The femoral nerve is the largest branch of the lumbar plexus; it passes under the inguinal ligament lateral to the femoral artery and divides into anterior and posterior branches soon after entering the thigh. The sensory divisions of the anterior branch, the intermediate and medial cutaneous nerves, supply sensation to the anteromedial aspect of the thigh. The motor division of the anterior branch innervates the pectineus and sartorius muscles. The posterior femoral branch gives off the saphenous nerve, which supplies sensation to the skin along the medial aspect of the lower part of the leg. The posterior branch also supplies motor function to the muscles of the quadriceps femoris group.8

The sciatic nerve is the largest peripheral nerve in the body. It arises from the sacral plexus. The sciatic nerve exits the pelvis through the greater sciatic foramen and travels through the posterior of the thigh; it extends from the inferior border of the piriformis to the distal third of the thigh. The sciatic nerve gives off articular branches that supply the hip joint. In the thigh, muscular branches innervate the adductor magnus and hamstring muscles. Just proximal to the popliteal fossa, the sciatic nerve divides to form the tibial and common peroneal nerves.9

Figure 53-4. The arterial blood supply of the femoral neck and head is provided to varying degrees by three sources: the ascending cervical arteries, the arterial branches within the marrow (not illustrated), and the dubious foveal artery within the ligamentum teres.
Pathophysiology

Fractures of the Femur and Hip

The pathophysiology of femur and hip fractures is discussed in the description of individual fractures. The vast majority of hip fractures occur in elderly patients with preexisting bone disease and result from relatively low-energy trauma, usually a ground-level fall. Major trauma such as motor vehicle collisions or falls from significant heights is responsible for a majority of fractures in young, otherwise healthy individuals.

Osteoarthritis of the Hip

As the population ages, a greater percentage of the population will suffer with the chronic pain associated with degenerative osteoarthritis of the hip. Overall, osteoarthritis ranks fourth in health impact in women and eighth in men in the western world. Disability often results from persistent pain and limited physical mobility. The progression of osteoarthritis can be demonstrated with serial radiographs of the affected hip (Fig. 53-5); however, radiographic findings do not necessarily correlate with symptoms.

Osteoporosis of the Femur

Osteoporosis is the leading cause of hip fracture. Osteoporosis currently affects more than 10 million people in the United States, and osteoporosis is projected to affect approximately 14 million adults older than 50 years by the year 2020. The number of hip fractures attributable to osteoporosis is expected to be 6.3 million by the year 2050, although the incidence in women is decreasing in recent years, probably because of an increased awareness and more aggressive treatment of osteoporosis. Hip fractures can have a devastating impact: One in five patients die during the first year after a hip fracture, mostly from causes other than the fracture itself; one third require nursing home placement after hospital discharge; and less than one third regain their pre-fracture level of physical function. The economic impact of these fractures is enormous.

The pathophysiology of osteoporosis is not completely understood, but strong associations with hormonal changes related to aging, genetic predisposition, vitamin D deficiency, lack of physical activity, and smoking have been recognized. Severe osteoporosis and hip fractures are most common in elderly white women; however, a decrease in bone density after age 30 is seen across all demographic groups. Radiography of the head of the femur can quantify the degree of osteoporosis, even in the nonfractured hip. The trabeculae of the femoral head and neck strengthen the bone and support the large mechanical forces produced across the hip joint. As osteoporosis begins and then progresses, these trabeculae disappear. This loss of trabeculae weakens the bone and increases the risk of fracture.

Avascular Necrosis

When a patient has an increasingly painful hip, buttock, thigh, or knee and no history of recent trauma, AVN of the femoral head should be considered. AVN has been referred to as aseptic necrosis, ischemic necrosis, and osteonecrosis. It is the result of ischemic bone death of the femoral head after compromise of its blood supply. AVN is bilateral in 52% of patients. It is common in relatively young patients, the mean age at diagnosis being 37 years. Although a specific etiologic disorder is not identified in 20% of the cases, known atrumatic causes include chronic corticosteroid therapy, chronic alcoholism, hemoglobinopathy (e.g., sickle cell anemia), dysbarism, and chronic pancreatitis. AVN necrosis also is an emerging complication associated with protease inhibitor therapy in patients infected with HIV (Fig. 53-6).

Traumatic AVN is a subacute manifestation after hip dislocation or femoral neck fracture. It is more common in males and African Americans. The incidence of AVN as a subacute complication of hip dislocation can reach 40%. Its development is clearly related to both the initial degree of trauma and the amount of time that the femoral head remains out of joint. Reduction of the hip within 6 to 12 hours after dislocation significantly decreases the incidence of AVN. For this reason, hip dislocation should be considered one of the few orthopedic emergencies. The emergency physician should perform reduction of the hip if there is any delay in orthopedic consultation.

Even with optimal treatment, femoral neck fractures are complicated by AVN in 11 to 19% of cases. For all practical purposes, femoral neck fractures are effectively intra-articular fractures. Acutely, bleeding from the fracture site may cause high intracapsular pressure and a tamponade effect on the femoral head, thereby further impairing the blood supply. In addition, if the bone fragments are not impacted, synovial fluid

Figure 53-5. Radiographic evidence for the development of osteoporosis or degenerative joint disease of the hip is demonstrated with serial radiographs in the same patient over several years. A, The symptoms initially are more dramatic than would be expected with the radiographic findings of increased sclerosis along the weight-bearing surface of the superior acetabulum. B, The joint space is lost. C, Erosion of the head and acetabular surfaces and reactive bony cystic changes are now evident.
Treatment of myositis ossificans is based on the RICE principle of rest, ice, compression, and elevation. Immobilization of the extremity may prevent retraction of ruptured muscle and increasing size of hematoma formation but should be limited to less than 48 hours. Once a stable scar has formed, range of motion within limits of pain should be initiated. Although indomethacin commonly is used to prevent heterotopic ossification after surgery, it has not been validated for the prevention as well as the treatment of myositis ossificans.18,19 Its use based on the principle of inhibiting bone formation does not seem to be contraindicated.18 Operative removal of a mature lesion may be indicated if the lesion is near a joint or is causing permanent impairment or pain (Fig. 53-7).

Calcifying Lesions of the Femur and Hip

Myositis Ossificans

Myositis ossificans (heterotrophic ossification) is pathologic bone formation at a site where bone is not normally found. Traumatic myositis ossificans results most commonly from a direct blow to muscle. The incidence of myositis after a direct blow has been reported as 9 to 17% and is thought to be related to the severity of the injury.18 The thigh and hip muscles are most commonly involved. Increased susceptibility to myositis ossificans has been described in persons with hemophilia or other bleeding disorders in conjunction with soft tissue injury.19 The incidence of myositis ossificans after hip surgery is approximately 2%, but these lesions are clinically significant in only 10 to 20% of cases.19

Bleeding into the muscle after trauma produces a local hematoma with subsequent new bone formation within the hematoma. This inappropriate response also may result from repeated minor trauma, for unknown reasons. Myositis ossificans should be suspected when symptoms persist past 10 to 14 days or if symptoms intensify several weeks after the trauma.19 The ossific mass often is palpable and may limit motion, depending on its location.

Radiographically, myositis ossificans appears as irregularly shaped masses of heterogeneous bone in the soft tissues around the joint or along fascial planes. It may be seen as early as 18 to 21 days after injury, but typically radiographic evidence lags behind onset of symptoms by weeks. Its appearance may simulate primary bone neoplasm, especially when the periosteum is involved. Osteosarcoma and periosteal osteogenic sarcoma should be considered in the differential diagnosis.

Treatment of myositis ossificans is based on the RICE principle of rest, ice, compression, and elevation. Immobilization of the extremity may prevent retraction of ruptured muscle and increasing size of hematoma formation but should be limited to less than 48 hours. Once a stable scar has formed, range of motion within limits of pain should be initiated. Although indomethacin commonly is used to prevent heterotopic ossification after surgery, it has not been validated for the prevention as well as the treatment of myositis ossificans.18,19 Its use based on the principle of inhibiting bone formation does not seem to be contraindicated.18 Operative removal of a mature lesion may be indicated if the lesion is near a joint or is causing permanent impairment or pain (Fig. 53-7).

Calcific Bursitis and Calcifying Peritendinitis

Calcification surrounding tendons and bursae or occurring in the joint capsule is referred to as calcific bursitis or calcifying peritendinitis. The cause of these lesions is unknown but may be similar to that of myositis ossificans. No relationship has been documented between the radiographic findings and acute symptoms. Calcific bursitis is uncommon, but when it does occur, it most frequently affects the trochanteric bursa of the hip (Fig. 53-8). Other possible affected areas include gluteal muscles and the hip flexors and adductors. The bursal calcification is seen on radiographs as an amorphous, poorly marginated line that is clearly separate from the cortex of the femur. Treatment should focus on stretching and strengthening of the hip.

Neoplastic Disease in the Hip

The most common neoplastic disease of bone is metastatic, generally from breast, kidney, lung, thyroid, and prostate tumors. Primary bone lesions also occur, with the most common
or known metabolic disorders should be noted. Any past steroid use is important to identify because it predisposes patients to AVN in the femoral head. A linear relationship has been recognized between the cumulative steroid dose and the incidence and severity of osteoporosis and hip fracture.21 Previous cancer, irradiation, and chemotherapy are clues to pathologic fractures.

True hip joint pain is groin pain, so a review of systems should include information that may help in ascertaining the etiology of both typical and atypical groin pain. Atypical pain here may be the result of nephrolithiasis, pelvic inflammation, infection or tumor, inguinal and femoral hernia, or adenopathy from genital or cutaneous infection. A history of low back pain may suggest radiculopathy as the cause of the patient’s pain. Elderly patients with a hip fracture sustained in a fall at home may be unable to summon help for hours to days. They often have severe dehydration, electrolyte abnormalities, rhabdomyolysis, and renal insufficiency and require a thorough evaluation of these metabolic parameters before surgery is considered.22 In addition, the reason for the fall should be determined if possible because it may reveal other comorbid conditions (e.g., syncope, cardiac dysrhythmias, polypharmacy, alcoholism). Sedative or antihypertensive medications predispose elderly patients to falling and should be prescribed carefully. Elderly patients may have sustained additional painful injuries in a fall, most commonly fracture of a vertebral body or wrist. A high index of suspicion for cervical spine and intracranial injuries also must be maintained. Young patients with a hip fracture resulting from high-energy mechanisms have concomitant injuries in 40 to 75% of cases.16 Pediatric patients with hip pathology will present with knee pain as the sole complaint.

**Physical Examination**

Management principles for injuries of the hip and femur are the same as those for traumatic injuries elsewhere in the body. Hypotension is a problem commonly encountered during the initial resuscitation of a multitrauma patient; however, hemorrhagic shock from an isolated femoral fracture should be a diagnosis of exclusion. Although up to 3 units of blood may be lost into the thigh with a femoral shaft fracture, with subsequent hypotension, cardiac, pulmonary, intra-abdominal,
and pelvic trauma must first be considered and excluded. Hypotension, neurovascular compromise, or suspicion for multiple injuries will necessitate transfer to a trauma center while initial stabilizing measures are being undertaken in the ED.

After other life-threatening conditions have been addressed, the injured extremity should be carefully evaluated. Visual inspection will reveal any pallor, ecchymosis, asymmetry, or deformity. Abrasions, lacerations, or open wounds are critical because their presence alters the management of concomitant fractures. The position that the leg assumes offers a clue to what may be found radiographically. In the presence of a displaced femoral neck fracture, the leg classically assumes the position of external rotation, abduction, and slight shortening. In intertrochanteric fractures, the leg is found in internal rotation with mild shortening. Shortening or a limb length discrepancy is found with fractures, dislocations, and osteoarthritis. Nondisplaced fractures, including stress fractures, will not produce limb shortening or rotation but will be painful on passive range of motion, particularly internal and external rotation. These fractures also will prevent the patient from being able to perform a straight leg raise. In patients with obvious deformities, range of motion should be deferred until after radiographs have been obtained.

Systematic examination will reveal any tenderness or warmth. Active and passive range of motion and muscle strength, though offering important information, frequently are limited by pain. Detailed neurovascular assessment is vital. Femoral nerve and arterial injury often occurs with subtrochanteric and femoral shaft fractures or anterior hip dislocation. The sciatic nerve can be injured with a hip fracture or anterior hip dislocation. Neurologic examination includes evaluation of light touch and pinprick sensation. Femoral, popliteal, dorsalis pedis, and posterior tibial pulses are assessed. Comparative blood pressures obtained by Doppler examination in the injured and uninjured extremities may be useful in diagnosing occult femoral arterial injuries. If the systolic pressure in the affected extremity is 90% or less (ratio less than 0.9) than that in the unaffected extremity, additional diagnostic studies should be undertaken. Additional diagnostic studies include Doppler flow ultrasound imaging, CT angiography, or angiography alone. The ankle-brachial index also can be similarly determined by comparing the systolic pressures of the affected extremity and of the ipsilateral arm. An index less than 0.9 necessitates further diagnostic studies.23

### DIAGNOSTIC STRATEGIES

#### Radiographic Anatomy and Evaluation

Normal radiographic and skeletal anatomy is familiar to emergency physicians (Fig. 53-11). One common inaccuracy merits clarification: The soft tissue linear radiolucencies superolateral and inferomedial to the femoral head and neck do not represent the hip capsule, as is commonly believed. Instead, they represent the fat within the fascial plane covering the gluteus minimus superiorly and the tendon of the iliopsoas muscle inferiorly.24 Comparison of these lines on the symptomatic side with those on the unaffected side should not be used to determine whether an effusion of the hip is present.

True anteroposterior and lateral radiographs of the femur usually are adequate for the evaluation of potential fractures. The femur should be in as much internal rotation as possible. The fracture line may be very subtle, particularly with femoral neck fractures. Experts have found three methods useful in identifying inconspicuous fractures. The use of Shentons’s line is described in a subsequent section on hip dislocations (see Fig. 53-24). (Lowell25 described a second method, which is illustrated in Fig. 53-15.) In searching for a fracture of the femoral neck, both the medial and lateral cortical margins of the femoral head and neck must be carefully examined for the normal S and reverse S curves seen on radiographs of nonfractured hips. The convex outline of a normal femoral head smoothly joins the concave outline of the femoral neck when in anatomic position. This produces an S curve and a reverse S curve regardless of the orientation of the radiographic projection. A fracture produces a tangential or sharp angle, indicative

---

**Figure 53-10.** Osteoid osteoma of the femur (solid black arrow). A, A large focal area of greater density than that of the surrounding femur represents both cortical and endosteal proliferation. The new cortical bone is smooth and sharply delineated, indicative of a nonaggressive process. The open arrow represents a bone island. B, A frontal-view tomosgram demonstrates an oval central radiolucent nidus (solid black arrow). (From Harris JH, Harris WH, Novelline RA: The Radiology of Emergency Medicine, 3rd ed. Baltimore, Williams & Wilkins, 1993.)
of disruption of the normal anatomic relationship. A third method, useful in the evaluation of seemingly unremarkable hip radiographs, is to trace the trabecular lines as they pass from the femoral shaft to the femoral head. These lines will be disrupted as they pass through the fracture site, and such disruption often provides the only if subtle clue. If a fracture is found, radiographs of the knee should be obtained as well. It is a basic orthopedic principle to image the joint above and below any fracture.23

Occult Hip Fracture

If radiographs do not show a fracture, the patient must be observed while ambulating. Inability to ambulate or difficulty in ambulation heightens the suspicion of occult fracture. Approximately 2 to 10% of all hip fractures are radiographically “occult” on plain films.26 Failure to detect these injuries results in increased mortality, risk of subsequent displacement of the fracture, and a higher incidence of AVN.27 When a painful hip prevents ambulation and plain radiographs do not reveal a fracture, magnetic resonance imaging (MRI) should be performed.26 In addition, elderly patients with unexplained chronic hip pain for more than 3 weeks may harbor an occult fracture even if they continue to ambulate. T1-weighted MRI will reveal fracture that was imperceptible at the time of injury with 100% accuracy and has been found to be cost-effective when compared with other strategies.27 A small study comparing CT scans against MRI in the diagnosis of occult hip fractures revealed a 66% misdiagnosis rate for CT scans.28 MRI remains the “gold standard” modality for diagnosing occult hip fractures and helps determine the treatment of these fractures (Fig. 53-12).

Bone scans have been useful in these patients, yet such scans lack adequate sensitivity. To identify most occult fractures, the scan must be delayed 72 hours after the injury. The intervening 3 days of bedrest and hospitalization until a bone scan can be performed are costly and not without risk. Various measures should be implemented to diminish the likelihood of deep vein thrombosis.

 MANAGEMENT

Patients with traumatic fracture of the hip or femur should have blood typed and crossmatched for administration of at least 2 units of blood. Hemodynamic instability may result from dehydration and blood loss of up to 3 units into the fracture site. The potential for significant blood loss and the multiple common associated injuries constitute important justification for this recommendation. Currently, treatment of these fractures is hemiarthroplasty or open reduction and internal fixation for femoral neck fractures. Internal fixation with a sliding compression screw generally is used to treat intertrochanteric fractures. The goal is to promote immediate postoperative mobilization. It has become widely accepted that the risks of surgery in elderly patients are minimal when compared with the risks of prolonged bedrest, deep vein thrombosis, pulmonary embolism, pneumonia, and urosepsis from an indwelling Foley catheter. If possible, the repair is conducted with use of spinal anesthesia to decrease the operative risk. Care of an elderly patient with a hip fracture requires a multidisciplinary approach and often involves coordination of the efforts of the emergency physician, orthopedist, internist, neurologist, and cardiologist to stabilize the patient before surgery. Operative repair should be performed after the patient is resuscitated and is in optimal preoperative condition.

Traction and Immobilization

Emergency rescue personnel often place a Hare splint or similar device that applies traction to the leg before transport if they suspect a femoral fracture. Although such management may provide pain relief and limit blood loss, great care must be given to the proper use of these devices. Prolonged traction during the assessment and management of other injuries can cause or worsen serious neurologic injury in the thigh. The traction used in the field for transport may produce potentially damaging tension on the nerve.

The femoral and sciatic nerves are much more likely to be injured from traction or during surgery than they are from a femoral fracture. Injuries considered to represent contraindications to the use of traction splints include pelvic injuries, patellar fractures or ligamentous knee injuries, and tibia or fibula fractures. Nonhospital health care and emergency rescue personnel should be instructed that traction should not be applied to any open fracture that has exposed bone. Such reduction pulls grossly contaminated bone fragments back into the wound before adequate debridement can be undertaken in the operating room. In patients with a suspected vascular
Figure 53-12. The patient complained of hip pain and could not ambulate. A, Initial radiographs failed to demonstrate a fracture. B, A magnetic resonance image revealed a femoral neck fracture through the compressive trabecular fibers.

and potential for ischemic necrosis of the femoral head. Accordingly, traction for proximal femur fractures should be discontinued once the patient arrives in the ED. The theoretical advantages for use of traction in the ED are pain control and fracture reduction, making operations easier to perform. A Cochrane systematic review looking at preoperative traction for fractures of the proximal femur in adults found no evidence to support these proposed advantages.

Open Fracture Care

By definition, an open fracture is any fracture in which a break in the integrity of the skin and soft tissue allows communication with the fracture and its hematoma. Any nearby wound or break in the skin must be considered to communicate with the fracture. Open fractures are divided into three categories (Table 53-2). Type I is characterized by the presence of endosteal or periosteal callus without a definite fracture line on plain radiographs; type II, a definite fracture is identified on plain radiographs, but no displacement; type III: the fracture is displaced.

Type I: endosteal or periosteal callus without a definite fracture line on plain radiographs; type II: a definite fracture is identified on plain radiographs, but no displacement; type III: the fracture is displaced.

*Any shotgun wound, high-velocity gunshot wound, segmental fracture, farmyard injury, vascular injury, or crush injury is classified as type III, regardless of wound size.

*Any shotgun wound, high-velocity gunshot wound, segmental fracture, farmyard injury, vascular injury, or crush injury is classified as type III, regardless of wound size.

Open wounds should be irrigated and then covered with sterile saline–moistened gauze.

For all type I open fractures, a first-generation cephalosporin should be administered intravenously. Types II and III require additional gram-negative coverage because of the amount of devitalized tissue and increased gram-negative skin flora found in the groin. This additional coverage could be provided by an aminoglycoside such as gentamicin or tobramycin. The use of perioperative first-generation cephalosporins has been shown to reduce postoperative infection even in closed fractures in patients who are to undergo surgery.

Great care should be taken to identify tetanus-prone wounds so that appropriate prophylaxis can be provided with tetanus immune globulin when indicated. Immunization status should be verified, especially in immigrant populations.
Compartment Syndrome

Because of the thigh’s larger volume, compartment syndrome within the thigh is far less common than in the lower part of the leg. When compartment syndrome does occur, only 50% of the cases are associated with a femur fracture. A large amount of bleeding into the compartment is required before the pressure rises above capillary perfusion pressure. It is difficult to clinically differentiate the expected swelling after an injury from early compartment syndrome. Clinical examination and the use of direct compartment pressure measurements can detect the development of compartment syndrome at an early stage.

Pain Management
Systemic Analgesia

It is well known that control of pain in EDs often is inadequate. Clinicians may be more reluctant to administer adequate doses of analgesics in elderly patients because of the potential for respiratory depression with narcotic medications. Nevertheless, pain control should be a high priority during the initial management period.

Femoral Nerve Block

Femoral nerve blocks have been used to treat femoral shaft fractures for more than 50 years. Despite proven effectiveness and a low complication rate, this technique has not been widely embraced by emergency physicians or surgeons. Femoral nerve block is invaluable as an adjunct or alternative to systemic analgesics in patients at risk for hypotension. It has been shown to significantly decrease time to lowest pain score as compared with intravenous narcotics, and patients have been found to require significantly lower doses of narcotics in conjunction with femoral nerve blocks. The block can be performed with the assistance of a peripheral nerve stimulator to localize the nerve; however, it also has been shown to be effective when performed by newly trained emergency physicians without the assistance of peripheral nerve stimulators. If a long-acting anesthetic such as bupivacaine is used, the expected onset of analgesia is 15 to 30 minutes, and its duration is 6 to 8 hours.

Careful neurovascular examination should be undertaken and documented before performing the femoral nerve block. After the nerve block procedure, continued assessment of the femoral muscular compartments is advisable to check for the development of compartment syndrome.

Hip Arthroplasty
Background and Epidemiology

Sir John Charnley first described the modern form of total hip arthroplasty (THA) in 1961. Despite many changes in both the design and materials used, Charnley’s essential design has been established as the standard. The number of THA procedures performed annually in the United States rose from 65,000 in 1982 to more than 234,000 in 2004. Women account for 62% of THAs in the United States. The most common indication for THA is joint failure resulting from severe osteoarthritis. Other indications include rheumatoid arthritis, certain types of hip fracture, AVN, and certain tumors. Arthritis associated with Paget’s disease, trauma, ankylosing spondylitis, and juvenile rheumatoid arthritis also are relative indications for THA or partial hip arthroplasty.

Outcomes and Complications

THA provides an immediate, substantial reduction of pain and improvement in functional ability and overall quality of life. A 10-year follow-up study of patient outcomes, including gait, perception of pain, physical mobility, sleep patterns, and energy scores, showed positive results in more than 90% of cases. Despite the tremendous success of THA, numerous complications have been reported, aseptic loosening of the prosthesis being the most common. Other complications include component wear, infection, surrounding femoral fractures, and deep vein thrombosis. Postoperative dislocation of the femoral component occurs in 1 to 3% of patients who have had primary THA and in 5 to 20% of patients who undergo revised THA. Generally, flexion past 90 degrees, adduction, and internal rotation place the hip at risk for dislocation. This combination can occur when patients bend at the waist (e.g., to sit on a normal low toilet or to get out of a chair) or cross the legs (Fig. 53-13).

Specific Injury Patterns

Fractures of the Hip and Femur

Avulsion Fractures

The pain of avulsion injuries of the hip may be manifested as referred pain to the thigh; these fractures are most common in adolescents and young adult athletes. The incidence of avulsion fractures is increasing as a result of the growth of competitive sports participation, especially in 14- to 17-year-olds. The muscular origin of this type of injury commonly involves the pelvic apophyses, which may not fully ossify until age 25. Avulsion at the site of the growth plate is the result of sudden
trochanteric, intertrochanteric, subtrochanteric, and shaft fractures), and degree of displacement. A working knowledge of the classification system will allow the emergency physician to communicate with the consulting orthopedist regarding the fracture’s pattern, stability, and treatment options.

**Femoral Neck Fractures**

**Pathophysiology.** Many experts now refer to femoral neck fractures as *insufficiency fractures* in acknowledgment of the major role played by osteoporosis. Age-related bone loss is believed to be the most important etiologic factor in femoral neck fractures. The theory that these fractures result from primary skeletal pathology is supported by the fact that minimal or no injury is associated with most of these fractures. Pathologic fractures from metastatic carcinoma are well described.

**Classification.** Fractures of the femoral neck originally were divided by location into subcapital and transcervical types. The subcapital fracture line lies just under the dome of the femoral head’s articular surface. Although several classification systems formerly were used to describe these fractures, they have been abandoned because of poor inter-rater reliability and limited clinical utility. Currently, femoral neck fractures should be classified as either nondisplaced or displaced fractures.

From 15 to 20% of all femoral neck fractures are nondisplaced fractures. The fracture line often may be very subtle. Techniques described for detection of subtle fracture lines may be useful for this reason. Evaluation of the continuity of the subcapital cortical lines, search for an indistinct broad band of increased subcapital density, and identification of the S and reverse S curves (Fig. 53-15) will lead to the correct diagnosis in most cases. In impacted femoral neck fractures, the neck cortex is driven into the cancellous femoral head. Bone impaction lends a certain inherent stability (Fig. 53-16). Because of this inherent stability, two different management approaches have been advocated: early ambulation and internal fixation. AVN, the most common complication, occurs in 20% of
patients regardless of the type of management. The prognosis for nondisplaced fractures is excellent; 96% of patients heal without complication. Without impaction, a nondisplaced femoral neck fracture possesses no inherent stability and will become displaced without internal fixation.

On initial evaluation, a patient with a displaced fracture of the femoral neck lies with the limb externally rotated, abducted, and slightly shortened. The diagnosis is confirmed with plain hip films. To avoid further disruption of the blood supply to the femoral head, range of motion should be deferred unless radiographs fail to reveal a fracture. In all displaced femoral neck fractures, the femoral head is rendered largely avascular, and signs of AVN and collapse may develop over the ensuing several years.

Treatment of these displaced fractures consists of either open reduction with internal fixation, hemiarthroplasty, or THA.

Outcome and Complications. The mortality rate during the first year after a femoral neck fracture is 14%, as compared with 9% for the control population. Factors affecting mortality include age, male sex, psychiatric illness, end-stage renal disease, and congestive heart failure. Institutionalized patients have a death rate three times higher. Complications can be minimized by early reduction, stable internal fixation, and early ambulation.

AVN and nonunion are the two major complications of femoral neck fractures. AVN is the most common complication, despite optimal treatment, because of the complex arterial anatomy. Deep infection in the form of osteomyelitis or septic arthritis is more common with femoral neck fractures because the fracture line extends into the joint. The rate of infection has been dramatically reduced with the use of perioperative antibiotics. Pulmonary embolism is another significant complication and is the leading cause of death 7 days after fracture in all orthopedic patients. Anticoagulation is recommended for at least 10 days after any hip surgery in patients without significant contraindications. Fondaparinux has been shown to be the most effective anticoagulant in this setting.

Intertrochanteric Fractures

Anatomy. The fracture line of intertrochanteric fractures extends between the greater and lesser trochanters of the femur. These injuries are considered to be extracapsular fractures. The fracture line extends through cancellous bone, which has an excellent blood supply. The hip’s short external rotators remain attached to the proximal femoral neck, and the internal rotators are attached to the distal end of the femur, thus explaining the position that the leg assumes with this fracture.

Pathophysiology. An intertrochanteric fracture in younger adults usually is the result of high-speed collisions or high-energy trauma, such as falls from heights. An elderly person may sustain this injury during a fall from any height. The fracture lines are the result of both direct and indirect forces. The direct forces act along the axis of the femur and on the greater trochanter as it strikes the ground. Indirect forces are produced as the iliopsoas pulls the lesser trochanter and the abductors pull the greater trochanter; these forces often cause fractures at the site of insertion.

Classification. A large number of classification systems for intertrochanteric fractures have been proposed to predict the possibility of achieving and maintaining stable reduction. A useful system, as borne out by our own clinical experience, designates the fracture according to the number of separate bone fragments produced (Fig. 53-17).

Management. Intertrochanteric fractures carry particular management pitfalls for the emergency physician. Great care must be taken to maintain focus on the entire patient and not on the fracture alone. Hemodynamic instability may result from
Pathologic Intertrochanteric Fractures

Aggressive treatment is indicated for patients who have pathologic intertrochanteric fractures or impending fractures if their life expectancy is more than a few months. Such treatment with subsequent radiation therapy improves the patient's quality of life, decreases pain, and improves mobility.

Isolated Fractures of the Greater or Lesser Trochanter

Fractures of the greater or lesser trochanter are rare. They occur in women more often than in men and are the result of a fall directly onto the trochanter or avulsion by the iliopsoas muscle. There may be a comminuted fracture involving only part of the greater trochanter or more subtle impaction of the lateral cortex. If avulsed, the fragments are displaced superiorly and posteriorly (Fig. 53-18).

Treatment consists of pain control and early mobilization with crutches; weightbearing is allowed as tolerated by pain. Outpatient management of this injury is possible with satisfactory support for home convalescence. The prognosis is good, and healing generally is excellent.

Subtrochanteric Fractures

Anatomy and Pathophysiology. Subtrochanteric fractures occur between the lesser trochanter and the proximal 5 cm of the femoral shaft. They may accompany intertrochanteric fractures. The subtrochanteric region is composed almost entirely of cortical bone, which lacks the vascularity important to new bone growth and repair. When fractured, it is more likely to be comminuted than bone with a higher cancellous content. Additionally, the greater portion of the biomechanical forces of the femur is transmitted down the curved medial cortex of the femoral shaft. If this cortex is disrupted, the metal hardware undergoes the majority of the stress. This mechanism accounts for the increased incidence of hardware failure when the medial cortex is largely involved.

These fractures characteristically are deformed because of the unbalanced muscle forces. The attachments of the iliopsoas, gluteal, and external rotator muscles consistently produce flexion, abduction, and external rotation of the proximal fragment.

Epidemiology. Subtrochanteric fractures account for 11% of all fractures of the proximal end of the femur. Although 10% of these fractures are caused by gunshots, the usual mechanism of injury is direct blunt trauma. A bimodal distribution for these injuries has been recognized. The first group consists of
elderly patients who experience a fall, in whom the fracture occurs through an area of weakened cortical bone. Pathologic fractures from metastatic lesions, Paget's disease, renal osteodystrophy, osteogenesis imperfecta, and osteomalacia are well-recognized clinical entities in these patients. The second group comprises victims of extreme high-energy trauma. In these patients, the subtrochanteric fracture is rarely an isolated injury because of the tremendous force required to produce it. Associated thoracic and abdominal injuries are common and must be aggressively sought to ensure adequate management. From 30 to 50% of patients with subtrochanteric fractures have associated fractures of the pelvis, spine, or other long bones. Stress fractures can occur in this region but are extremely uncommon.

Classification. A variety of classification systems for these fractures have been proposed, although none are widely accepted. From a practical standpoint, it is best to define and describe these fractures by location (proximal or distal), angle (transverse, oblique), and the presence of comminution (Fig. 53-19).

Management. Hemodynamic instability may result from blood loss of up to 3 units into the fracture site. Although such blood loss can lead to hypovolemic shock, other causes of hypotension in a trauma patient must be investigated. Open fractures are rare and, when present, are accompanied by significant soft tissue injury. Vascular and neurologic injuries also are uncommon.

Definitive management of subtrochanteric fractures is a complex issue. Maintaining limb length and controlling rotation are difficult. Open reduction with internal fixation generally is the treatment of choice. However, in the rare case with severe comminution or an open, grossly contaminated fracture, nonoperative management may be preferable. Children younger than 10 years also may be managed nonoperatively. The amount of remodeling and growth stimulation occurring in children of this age usually ensures good results without internal fixation.

Outcomes. The bone in the subtrochanteric region is largely cortical and relatively avascular when compared with the cancellous intertrochanteric region. It logically follows that healing is comparatively slow. Comminution is common and increases the likelihood of nonunion. Comminuted and distal subtrochanteric fractures carry a worse prognosis.

Complications include fat embolism in all patients and the adverse effects of prolonged immobilization in the elderly. Reported mortality rates from subtrochanteric fractures range from 9.6 to 13.3%. The violent force and common associated injuries contribute to the high mortality among patients who sustain these fractures.

Femoral Shaft Fractures

Pathophysiology. Femoral shaft fractures are common injuries in young adults after high-energy trauma. As is the case with other femoral cortical fractures, considerable violent force is required to produce a fracture in a normal shaft. Automobile and motorcycle accidents, falls, and pedestrian accidents account for a majority of femoral shaft fractures. The femoral shaft usually fails under tensile strain, and a transverse fracture results. Higher forces produce varying degrees of segmental or comminuted. Open fractures of the femoral shaft are less frequent and are often the result of a gunshot wound. Pathologic fractures occur from a torsional stress that produces a spiral fracture.

Classification. There is no commonly accepted or easily remembered classification for femoral shaft fractures. Location and geometry of the fracture line should be used to describe these fractures. Transverse, oblique, spiral, wedge, and comminuted are useful terms for describing these fractures.

Clinical Features. Patients often arrive in the ED with the injured extremity immobilized by traction devices, which should be removed while maintaining immobilization of the limb. Neurovascular injuries are rarely associated with closed femoral shaft fractures. Significant hemorrhage into the thigh can occur with a femoral shaft fracture, just as it can with
intertrochanteric and subtrochanteric fractures. Injuries commonly occurring in the presence of femoral shaft fractures include hip fractures, fracture-dislocations, femoral neck fractures, supracondylar femoral fractures, and patellar fractures. Almost half of femoral shaft fractures have associated ligamentous damage in the knee. If the patient has a femoral fracture, pain often prevents adequate evaluation of knee stability. Any attempt to evaluate the stability of the knee acutely will result in additional pain and hemorrhage without providing useful, reliable information.

**Management.** Internal fixation with intramedullary rods has been demonstrated to shorten both hospitalization and total disability time with most femoral shaft fractures. The vast majority of femoral shaft fractures heal well in time, regardless of the mode of treatment. Severely comminuted fractures are more likely to be treated by closed reduction.

**Outcomes.** Femoral shaft fractures have close to a 100% union rate, and most patients are able to return to work after approximately 6 months. Even a minor degree of limb shortening or malalignment can lead to posttraumatic arthritis. Refracture is a rare occurrence that is most likely at two times during the healing process: during early healing and callus formation or during the brief period after the hardware is removed. After the hardware removal, the unsupported bone is required to bear the entire weight of axial loading and is at risk for refracture.

### Fractures with Minimal or No Trauma

Most patients who arrive in the ED with hip or thigh pain will provide a clear history of a traumatic event. Hip or knee pain in the young, in athletes, and in the elderly deserves investigation, even when minimal or no trauma has been reported. This patient population commonly has occult hip pathology and occasionally femoral pathology. Although senile osteoporosis is the leading cause of femoral neck fractures after minor trauma, pathologic fractures of the femur may result from metastatic, metabolic, or endocrinologic disease. The incidence of fracture in patients with hyperthyroidism is 12%.57

### Stress Fractures

**Pathophysiology.** Stress fracture of the femoral neck was first reported in 1905 by Blecher.58 Stress fractures occur when normal bone is repeatedly subject to submaximal forces. This recurring stress stimulates the bones to remodel and strengthen. In a stress fracture, osteoblasts are unable to lay down new bone and remodel fast enough, so the bone fails. Stress fractures can also occur in diseased bone when it is subjected to repeated minimal stress.

**Clinical Features.** The symptoms of a stress fracture of the femoral neck often are so subtle that they may be mistaken for muscle strain or an overuse injury. Early symptoms frequently include morning stiffness and aching in the hip on the first steps after a period of rest. The pain gradually increases during prolonged exercise and may reach the point at which bearing weight becomes impossible. Pain is felt in the groin or along the medial aspect of the thigh toward the knee.

On examination, a painful limp is obvious. This painful or antalgic gait is characterized by shortening of the stance phase of the injured extremity. No obvious external rotation or shortening of the leg is seen; the patient experiences only minor discomfort with active or passive motion, except at the extremes of flexion and internal rotation. Tenderness is minimal because of the large amount of soft tissue coverage at the femoral neck.

**Diagnostic Strategies.** Radiographs are helpful if they demonstrate a fracture, but findings often are negative until 10 to 14 days after the injury. Endosteal or subperiosteal callus develops at the fracture site during this period. In addition to the standard anteroposterior and lateral views of the hip, oblique views may delineate the fracture line. Close attention should be paid to the trabecular fibers of the femoral neck. A stress fracture often can be identified as an isolated disruption of either the tensile (lateral aspect of the femoral neck) (Fig. 53-20A) or the compressive (medial aspect of the femoral neck) (Fig. 53-20B) trabecular fibers. If a fracture is suspected clinically but radiographic findings are negative, the next step is MRI. If a fracture is found, the contralateral hip should be extensively evaluated because of the significant incidence of bilateral stress fractures.

**Management.** Treatment of stress fractures of the femoral neck is determined by the involvement of the compressive or tensile aspect. Compressive-side fractures involving less than half of the cortex are inherently stable and can be treated conservatively with partial weightbearing with crutches. Tension-side fractures and compressive-side fractures involving more than half the cortex are considered unstable and at risk for displacement. These fractures should be treated operatively with screw fixation.

**Other Causes of Pain**

Considerations in the diagnosis of atraumatic pain of the hip and thigh are listed in Box 53-1.

### Dislocations and Fracture-Dislocations of the Hip and Femur

**Injury Patterns**

Epidemiologists have identified injury patterns in victims according to the mechanism of injury. Pedestrians who are struck by a car have head, chest, pelvic, arm, and femur injuries. Motorcyclists tend to sustain pelvic and ipsilateral leg injuries. A person who stumbles and falls seldom has major associated injuries. Each of these main categories of injury is discussed next.

**Hip Dislocations**

Dislocations and fracture-dislocations of the hip are two of the few true orthopedic emergencies. The hip joint possesses
Differential Diagnosis of a Painful Hip

**PART II**

**Trauma**

Section Three

**Orthopedic Lesions**

Major trauma victims. In the presence of this type of injury, patients be managed as acetabulum is used to classify dislocations into anterior, forcefully hyperextended. May also result from a fall or sports injury when the hip is hip abducted and externally rotated at the time of impact. It occurs after a motor vehicle crash when the occupant has the head up out of the acetabular cup. Such dislocation most often external rotation of the femoral head. These forces lever the anterior dislocations result from forceful extension, abduction, and sufficient force, the femoral head dislocates posteriorly. Anterior (Fig. 53-22) or laterally toward the pubis (pubic dislocation). Central dislocations, which occur in 2 to 4% of cases, are not true dislocations because the entire femoral head is forced centrally through a comminuted fracture of the acetabulum. Inferior dislocation (luxatio erecta) of the hip is a very rare condition that occurs almost exclusively in children younger than 7 years of age.

**Mechanism and Biomechanics.** Traumatic hip dislocations occur primarily in patients sustaining severe multisystem trauma, most often as a result of high-speed motor vehicle crashes. Failure to use seat belts is a significant risk factor. Other less common mechanisms include falls, sports injuries, and pedestrians struck by automobiles.

Posterior dislocations are almost always the result of motor vehicle crashes. A seated vehicle occupant typically has the hip adducted, flexed, and internally rotated at the time of impact. As the knee strikes the dashboard, the force is transmitted through the femoral shaft to the femoral head. With sufficient force, the femoral head dislocates posteriorly. Anterior dislocations result from forceful extension, abduction, and external rotation of the femoral head. These forces lever the head up out of the acetabular cup. Such dislocation most often occurs after a motor vehicle crash when the occupant has the hip abducted and externally rotated at the time of impact. It may also result from a fall or sports injury when the hip is forcefully hyperextended.

**Classification.** The relationship of the femoral head to the acetabulum is used to classify dislocations into anterior, posterior, central, and inferior types. A fracture-dislocation includes an associated fracture of the acetabulum or femoral head. Posterior dislocations (Fig. 53-21) account for 80% to 90% of cases. Anterior dislocations (Fig. 53-22) are seen in 10 to 15% of patients. In anterior dislocations, the femoral head may dislocate medially toward the obturator foramen (obturator dislocation) (Fig. 53-23) or laterally toward the pubis (pubic dislocation). Central dislocations, which occur in 2 to 4% of cases, are not true dislocations because the entire femoral head is forced centrally through a comminuted fracture of the acetabulum. inferior dislocation, (luxatio erecta) of the hip is a very rare condition that occurs almost exclusively in children younger than 7 years of age.

**Clinical Features.** The position of the injured extremity may provide valuable clues in the evaluation of a hip dislocation. A patient with a posterior dislocation typically holds the hip flexed, adducted, and internally rotated. The knee of the affected extremity rests on the opposite thigh. The extremity generally is shortened, and the greater trochanter and buttock may be unusually prominent. By contrast, a patient with an anterior dislocation holds the hip in abduction, slight flexion, and external rotation. These physical findings may be absent in patients with an associated ipsilateral femoral shaft fracture.

The neurovascular examination should focus on the sciatic nerve and femoral vessels. Sciatic palsies are present in approximately 10% of patients with hip dislocation and most commonly involves the peroneal nerve branch. The most sensitive clinical sign of peroneal nerve palsy is weakness of the exten-
or hallucis longus; other signs include weakness of dorsiflexion and numbness or tingling over the dorsum of the foot. The femoral vessels and nerve are particularly prone to injury after an anterior dislocation.

**Diagnostic Strategies.** Radiologic investigation begins with an anteroposterior view of the pelvis. This view alone will identify a majority of hip dislocations. An anteroposterior pelvis film should be obtained in all trauma patients with the aforementioned deformities. The anteroposterior radiograph should include the entire pelvis and the proximal third of the femur to allow comparison of both hips. When a dislocation is found or suspected, a lateral view of the hip will provide additional definition of the injury.

Although most hip dislocations are seen clearly with these two views, several more subtle radiographic signs may assist physicians in making a confident diagnosis. The first indicator involves the position of the lesser trochanter. Because a posteriorly dislocated hip is internally rotated, the lesser trochanter is superimposed on the femoral shaft and is not seen on the anteroposterior projection. By contrast, an anteriorly dislocated hip is externally rotated and the lesser trochanter appears in profile. The second clue is found in the size of the femoral head. Because a posteriorly dislocated hip is closer than the unaffected side to the x-ray cassette, it appears smaller. The converse is true in anterior dislocations, in which the hip is farther from the x-ray cassette than the contralateral side and thus appears larger. The third finding relates to the integrity of Shenton’s line (Fig. 53-24). This line is a smooth, curved line drawn on the radiograph along the superior border of the obturator foramen and medial aspect of the femoral metaphysis. Disruption of this line should raise suspicion of a femoral neck fracture or hip dislocation.

An obvious dislocation may distract the emergency physician from a search for concomitant fractures. Examination of the trabecular pattern can identify associated fractures of the acetabulum and femoral head, neck, or shaft. It is important to identify acetabular fractures before closed reduction is attempted because intra-articular bone fragments may interfere with reduction. Although these fractures may make the reduction more difficult, their presence is not a contraindication to reduction.

**Management.** Hip dislocations constitute a true orthopedic emergency, and reduction should be performed within 6 to 12 hours. The earlier the reduction, the better the results. The incidence of AVN, traumatic arthritis, permanent sciatic nerve palsy, and joint instability logarithmically increases with the length of time for which the hip remains dislocated.

The timing and method of reduction are dependent on the overall condition of the patient, the type of dislocation, and the presence or absence of associated fractures. In cases of simple dislocation, closed reduction should be attempted first. Although some clinicians recommend that this procedure be performed with the patient under general anesthesia, this delay, with its associated increase in the rate of AVN, is not warranted when moderate sedation in the ED is readily available. If the emergency physician chooses to attempt closed reduction, the principles of moderate sedation and monitoring should be followed. The primary contraindication to closed reduction is the presence of a femoral neck fracture. Another relative contraindication is the presence of fractures in the dislocated extremity, because such fractures preclude application of traction to the limb. Techniques of closed reduction are described next.

**Reduction Techniques.** The Stimson technique and the Allis technique are the methods most commonly used for reduction of posterior hip dislocations (Fig. 53-25). The Allis technique usually is effective for both posterior and obturator dislocations (Fig. 53-26). It is perhaps the most commonly used method for hip reductions in the ED.

**Allis technique for reduction of posterior hip dislocation**
1. The patient is placed in the supine position, and the pelvis is stabilized by an assistant.
2. With the knee flexed, the operator applies steady traction in line with the deformity.
3. The hip is slowly brought to 90 degrees of flexion while steady upward traction and gentle rotation are applied.
4. The assistant pushes the greater trochanter forward toward the acetabulum.
5. Once reduction is achieved, the hip is brought to the extended position while traction is maintained.

Stimson technique for reduction of posterior hip dislocation

1. The patient is placed prone with the leg hanging over the edge of the bed. The hip and knee are flexed at 90 degrees.
2. An assistant stabilizes the pelvis.
3. The operator applies steady downward traction in line with the femur.
4. The femoral head is gently rotated, and the assistant pushes the greater trochanter anteriorly toward the acetabulum.
5. Once reduction is achieved, the hip is brought to the extended position while traction is maintained.

Other recently described techniques for closed reduction of posterior hip dislocations include the Rochester method, the Whistler method, and the traction-countertraction technique.

Closed reduction of a pubic dislocation can be quite difficult. The anterior position of the femoral head will resist flexion, making the Allis technique impossible. We recommend reduction with the following sequence of maneuvers.

Technique for reduction of pubic dislocation

1. The patient is placed in the supine position.
2. Longitudinal traction is applied in line with the deformity.
3. The hip is hyperextended and internally rotated as an assistant applies downward pressure on the femoral head.

Although prompt anatomic reduction is clearly desirable, multiple attempts at reduction in the ED should be avoided. Difficulty with reduction usually is the result of incarceration of a tendon, a capsular structure, or an unrecognized osteochondral fragment that is blocking reduction. In the case of an irreducible dislocation, closed reduction with the patient under general anesthesia or an open reduction procedure often is required.

Postreduction Management. After closed reduction, the hip should be tested for stability, which is accomplished by gently taking it through a full range of motion to see whether it will redislocate. After testing has ensured stability, the injured extremity should be placed in a knee immobilizer and an abduction pillow should be applied to prevent repeat dislocation. An anteroposterior radiograph of the pelvis should be obtained to verify the adequacy of reduction. The radiograph should be carefully inspected to verify that the femoral head is in the acetabulum, the shaft of the femur is in neutral position, Shen-
Figure 53-28. **A**, A fracture through the femoral head is seen with this anterior hip dislocation. **B**, Incomplete reduction is identified by examination of the joint space. This space should be the same width as in the unaffected joint. Asymmetry signals an entrapped intra-articular fragment, which should be verified by computed tomography scan.

Figure 53-29. **A**, Anterior hip dislocation is identified as the lesser trochanter is brought into profile. Note the fracture of the lateral aspect of the greater trochanter. **B**, A postreduction radiograph demonstrates adequate reduction with symmetrical joint spaces.

Fracture-Dislocation of the Femoral Head

Epidemiology and Mechanism. A small subset of hip dislocations are associated with fractures of the femoral head (Fig. 53-29A). Femoral head fracture occurs in 22 to 77% of anterior hip dislocations and in 10 to 16% of posterior hip dislocations. These injuries are almost always the result of high-speed vehicular trauma. Because of the tremendous force required to produce this injury pattern, coexistent multisystem trauma is the rule.

When a femoral head fracture and hip dislocation coexist, patients assume the position typical for the dislocation. Hip mobility is markedly reduced, and pain usually is severe. After initial stabilization, the involved extremity should be carefully examined for associated fractures of the femoral shaft and knee. The neurovascular examination should assess for femoral or sciatic nerve injury. Radiographs should be evaluated carefully for any femoral head fracture in all patients with hip dislocations. Evidence for fracture of the femoral head can be subtle. These fractures may be detected on radiographs by following the curve of the dislocated head and the acetabular cup to search for a small fragment that may otherwise be overlooked. Known or suspected injuries can be further defined by CT or MRI.

In most cases, satisfactory results can be obtained with closed reduction (see Fig. 53-29B). Several experts recommend obtaining a CT scan of the hip before closed reduction to further define the injury and locate fracture fragments. If the hip cannot be reduced by manipulation or if reduction of the femoral head fragment is unsatisfactory, open reduction will be required.

Dislocation of Hip Prosthetics

An increasing number of patients have undergone hip arthroplasty. In addition to those procedures performed for treatment of femoral neck fractures, more than 230,000 patients undergo elective primary THA each year. Postoperative dislocation of the prosthesis is a common complication that occurs in 1 to 3% of patients with primary THA and in 5 to 20% of patients with a revised THA. Although most dislocations take place within 3 months of surgery, “late dislocations” have been reported up to 10 years after the operative procedure; such dislocations can result from major trauma or from trivial events (e.g., rising from a seated position). Posterior dislocations account for 75 to 90% of cases (see Fig. 53-13). Reduction techniques for prosthetic hip dislocations are identical to those described earlier. Consultation with an orthopedic surgeon is essential for safe reduction and development of a
long-term treatment plan for the patient. Reduction of the prostheses does not carry the same urgency as for reduction of a dislocated hip because there is no risk for the development of AVN once the femoral head has been replaced. Traction on the sciatic nerve can occur, however, making early reduction more compelling. In addition, the reduction itself carries the unique dangers of loosening of the components, fracturing of the surrounding bone, and movement of the acetabular cup; reduction is best performed with an orthopedic consultant.

Soft Tissue Injuries

Soft tissues may be subject to muscle or tendon strain or contusions from misuse, overuse, or accidental trauma. Rupture, hemorrhage, or myositis ossificans may develop in muscles.

Muscular Injuries

Strenuous exercise in a poorly conditioned person, sudden exertion, and direct trauma all may traumatize soft tissues. Cold temperature, vascular or infectious disease, fatigue, and poor training are known predisposing conditions for this injury. Predisposing infectious diseases include trichinosis, tuberculosis, and typhoid fever.

A detailed classification system of muscular injuries has been devised, but it is of little clinical significance for the emergency physician. Classification of complete and partial tears is reasonable and of greater clinical utility. Partial tears are reversible injuries that are aggravated by movement or tension. Mild spasm, swelling, ecchymosis, and tenderness cause minor loss of function and strength. Complete tears produce a palpable depression, and the torn muscle edge also is often palpable. Other possible findings include severe spasm, swelling, ecchymosis, tenderness, and loss of muscle function. In significant muscle strains, radiographs are needed to evaluate for the possibility of an accompanying bone avulsion injury.

Initial management of incomplete tears traditionally includes the local application of ice for the first 48 hours, followed by heat. Compressive wraps cause distal venostasis with the potential for distal venous clot formation and do not significantly decrease recovery time. A regimen of nonsteroidal anti-inflammatory agents to achieve sufficient analgesia is important for recovery and patient satisfaction. Muscle relaxants may be useful when the injury is accompanied by muscular spasm. In general, complete rest of the affected muscle should be maintained, with the recommendation of “weightbearing as pain tolerated.” This progressive muscle loading can be started within 3 to 5 days once sufficient scar has formed. In order to prevent reinjury, the muscle loading should be limited by the patient’s pain. Any patient with significant injury should be referred for physical therapy.

A complete muscle tear is a serious condition. Consultation plus follow-up care with an orthopedic surgeon or sports medicine specialist is vital for these patients.

Sports Injury Patterns

Athletes commonly experience muscular injury from accidents and overtraining. The two most common injuries involve the hamstrings and the quadriceps.

The Hamstrings

Hamstring muscle strains are common in sports involving running and sudden acceleration. The injury is accompanied by sudden intense pain in the posterior of the thigh. Any active or passive motion at the hip is poorly tolerated because of the intense pain that movement causes. Ischial avulsion fractures can occur, and pelvic radiographs should be obtained if the exam reveals bony tenderness. Crutches and toe-touch weight-bearing are recommended until the patient is evaluated by a physician trained in sports medicine. Toe-touch weightbearing refers to walking with crutches while the toes of the injured extremity rest on the ground without placing any weight on it. Appropriate weight-training programs have been shown to speed rehabilitation of this injury. Complete recovery from a hamstring muscle strain may take weeks to months.

The Quadriceps

The quadriceps is the most common muscular group to sustain complete tears. This injury occurs when the muscles are contracted suddenly against the body’s weight, as may occur when an athlete slips or stumbles and attempts to avoid a fall. Ambulation is significantly affected. There is pain with active and passive knee extension. In significant tears, the patient may be unable to actively extend the knee or maintain its extension against gravity. A palpable depression just proximal to the superior pole of the patella suggests a complete tear. It is imperative to document an intact patellar mechanism on exam, because a complete tear of the quadriceps most often requires surgical repair and extensive rehabilitation.

Iliopsoas Strain

Gymnasts and dancers are the group of athletes most likely to experience an injury to the iliopsoas as a result of sudden forceful hip flexion against resistance. Severe pain often is experienced in the groin, thigh, or low back region. Severe intra-abdominal pain is common at the muscle origin and may dominate the clinical picture. Examination reveals groin tenderness and pain with active hip flexion. Radiographs of the femur should be obtained to identify an avulsion fracture of the lesser trochanter. CT frequently will demonstrate a large hematoma. Bedrest with partial flexion at the knee and hip generally is required for 7 to 10 days. With severe strains, symptoms may persist for 2 to 3 months.

Hip Adductor Strain

Injury to the hip adductors occurs as the thigh is forcefully abducted, as in a straddle injury. The patient complains of pain in the groin, the pubic region, and the medial proximal aspect of the thigh. Abduction and adduction often are limited because of pain. Swelling and skin discoloration may confirm presence of the tear. If the tear is complete, a defect in the muscle may be felt by the examiner along the medial aspect of the thigh near the groin. Treatment is conservative, with patients initially benefitting from rest, with gradual progression in a stretching and strengthening program.

Gluteus Muscle Strain

The gluteus muscles may be injured with vigorous or forced hip extension, as seen in track-and-field jumping events. The pain typically is less severe than that associated with injuries to other muscle groups. The hip is tender when extended or abducted.

Tendon Injuries

Clinically, tendon strains tend to have a more insidious onset than that typical for muscle strains. These strains may occur at the attachment of the muscles to the superior or inferior pubic ramus, the pubic symphysis, the ischium, and the femur.

A groin pull is the lay term for an injury to the tendons of the hip adductors. One study found adductor strains to be the most common groin injury in athletes, with 62% of the cases...
involving the adductor longus muscle. The adductor magnus and brevis and the pectineus often are involved as well. It commonly occurs in skaters and cross-country skiers when an accidental stress abducts the thigh during a powerful contraction of the adductors. These muscles also may be injured from overuse in an unconditioned patient. Local pain is noted at the inferior pubic ramus and the ischial tuberosity. Extension, abduction, and adduction of the hip are painful. The pain may radiate to the back of the thigh.

Pain over the greater trochanter may represent tendon strain of the attachments of the gluteus medius, glutaeus minimus, tensor fasciae latae, or piriformis. The pain is aggravated by resisted abduction. Tenderness in the groin and painful hip movement suggest a strain of the iliopsoas tendon at its attachment to the lesser trochanter. Trochanteric bursitis, peritendinitis, AVN, neoplasm, and other causes should be considered.

Treatment of a tendon strain is similar to that for other soft tissue injuries. The use of crutches with weightbearing as tolerated by pain is helpful for the first 2 weeks. Opioid analgesics and a short course of anti-inflammatory agents should be given. Complete tendon disruption may require surgical repair.

Osteitis Pubis

Osteitis pubis is a poorly understood disorder. It is characterized by pubic symphysis pain and joint disruption and is most common in distance runners and soccer players. The adductor muscles act as a “compression strut,” displacing forces across the hip. The most likely mechanism is repetitive pulling of the adductor muscles, causing increased shearing at the pubic symphysis.

Clinically, patients present with groin pain of insidious onset, with most reporting pain at the symphysis and adductor muscles. Pain usually can be elicited on palpation of the symphysis and also can be provoked by adduction of the hip or by sit-ups. Plain radiographs show widening of the symphysis, irregular contour of the articular surfaces, or periarticular sclerosis (a late finding) (Fig. 53-30). These features are not specific and in one study were seen in 76% of asymptomatic soccer players. MRI is the imaging study of choice and will show marrow edema on T2 images early in disease. Osteitis pubis has been associated with spontaneous cases of pubic symphysis osteomyelitis and should be considered in the differential diagnosis.

Treatment is conservative, and in most cases the process is self-limited. Patients benefit from activity modification, good shoe wear, and therapy addressing flexibility and strength of the pelvic and hip musculature. Average time to heal has been reported at 9 months.

Vascular Injuries

Hip dislocations and the various types of femoral fractures may have an associated arterial injury. The vessel may be partially lacerated, completely severed, or thrombosed. Lack of distal arterial flow may also represent a stretched vessel in spasm. The superficial femoral artery is most commonly injured with trauma to the hip and thigh. The common and the deep femoral arteries are less frequently injured. In the acute setting, penetrating trauma is the usual mechanism of injury.

Arterial injury with femoral shaft fractures is rare. Anterior- and superior-type dislocations may produce femoral artery injury.

Comparative blood pressures obtained by Doppler examination in the injured and uninjured extremities may be useful in suspected arterial injuries. If the systolic pressure in the affected extremity is 90% or less (index less than 0.9) than that in the unaffected extremity, additional diagnostic studies should be undertaken. The ankle-brachial index also can be similarly determined by comparing the systolic pressures of the affected extremity and of the ipsilateral arm. An index less than 0.9 necessitates further diagnostic studies. Additional diagnostic studies include Doppler flow ultrasound imaging, CT angiography, and angiography alone. CT angiography, however, is becoming more prevalent, with recent studies showing 96% and 97% sensitivity and specificity, respectively, when compared with conventional radiography.

Diagnostic evaluation must not delay surgical exploration when clinical signs and symptoms of vascular injury are obvious. These hard signs and symptoms of injury include active or pulsatile hemorrhaging, expanding or pulsatile hematoma, diminished or absent pulses, auscultated bruit or palpable thrill, and evidence for limb ischemia. Early restoration of blood flow is essential to prevent ischemic damage to the leg.

Neurologic Injuries

Trauma, infectious agents, and degenerative disease all may injure peripheral nerves. In trauma, nerves may be injured by a blunt object that causes a contusion, by a sharp penetrating object that produces a partial or complete tear, or by the stretch of a missile as it passes in proximity. Nerves are particularly vulnerable to prolonged ischemia, which can lead to necrosis. Compression of the nerve from a hematoma or a displaced femoral head may also appear as a neurapraxia manifested by transient loss of conductivity. The femoral and sciatic nerves are rarely injured with femoral shaft fractures because they are encased in muscle throughout the length of the thigh.

Treatment of neurovascular compromise from a hip dislocation or a displaced femoral fracture consists of immediate reduction to ensure limb viability. Whenever possible, reduction should be accomplished before transfer of the patient to another treatment center.
When the femoral nerve is injured, the iliac and femoral arteries are commonly involved because of their anatomic proximity. If injured, the femoral nerve most often is traumatized in penetrating trauma of the pelvis, groin, or thigh. Femoral neuropathy occasionally can result from compression by a hematoma within the abdominal wall or the iliopsoas as a complication of hemophilia, anticoagulant therapy, or trauma.\textsuperscript{83}

The motor deficit in complete femoral neuropathy is manifested as marked weakness of knee extension. The patient is able to walk on level ground yet has extreme difficulty walking up stairs or an incline. Patients cannot rise from a sitting position because of significant proximal muscle weakness. The sensory deficit varies but is localized along the anterior aspect of the thigh and medial lower aspect of the leg. The most reliable spot for testing for a sensory deficit is just superior and medial to the patella. The deep tendon reflex of the knee will be diminished or absent with such deficits.

If a traumatic neuropathy is suspected, immediate orthopedic consultation should be obtained. Nerve exploration and repair generally are preferred for penetrating trauma and when direct impingement on the nerve by bone fragments or hematoma is suspected. Surgical exploration and drainage of a hematoma that is impinging on the femoral nerve are appropriate.

Progressive nontraumatic neuropathies warrant urgent neurologic consultation. With a chronic neuropathy, atrophy of the anterior aspect of the thigh will already have developed. The motor deficits have been discussed previously.

Sciatic Nerve

Sciatic injury is rare with femur fractures, but it may be the result of traction used to stabilize the fracture during the initial management period. Complete traumatic injury may result from a deep penetrating wound in the hip, thigh, or buttock. Sciatic nerve palsy either from inadvertent injection into the nerve or secondary to intraneural or extraneural hemorrhage in patients taking anticoagulants has been described. Posterior hip dislocations and fracture-dislocations produce sciatic neurapraxia in 10 to 14% of these injuries.\textsuperscript{23,65} Patients with complete sciatic neuropathy have paralysis of the hamstring muscles and all muscles below the knee. With partial injury, a peroneal palsy with weakness of the extensor hallucis longus muscle is the most sensitive clinical sign. There is sensory loss below the knee and along the posterior of the thigh. The deep tendon reflex at the ankle is absent or diminished.

Sciatic injury from posterior dislocations often consists of only transient loss of conductivity, particularly in motor fibers. Unfortunately, the other injury patterns to the sciatic nerve carry the worst prognosis of all peripheral nerve injuries. The prognosis is poorest when the injury is proximal and complete. Even with optimal repair, recovery often is inadequate. Sciatic neuropathy is a disabling problem.

Obvious atrophy of the lower part of the leg and foot develops, followed by ulceration of the sole of the foot and infection. A below-the-knee amputation frequently is necessary in these cases.

\section*{SPECIAL PEDIATRIC CONSIDERATIONS}

\subsection*{Anatomy}

Development of the femoral head and neck with its growth plates and two primary ossification centers is illustrated in Figure 53-31. A significant proportion of the pediatric hip is radiopaque cartilage and developing new bone. For this reason, almost any type of trauma in this location carries the potential for premature growth arrest. Recognition that large portions of the pediatric hip are radiolucent will counter the tendency to focus attention on the ossified elements.

\subsection*{Hip Dislocation}

The incidence of hip fractures and dislocations is increasing in young patients, often as a result of high-energy trauma. Up to 50% of children with a hip dislocation also will have fractures elsewhere. In small children, dislocation of the hip is more common than femoral neck fractures. The force required to dislocate a pediatric hip is much less than that required in an adult because the acetabulum is less completely developed than in adults. Seemingly negligible trauma, such as tripping or a minor fall, may dislocate the femoral head in a young child. In a school-age child, athletic injuries are the major cause of traumatic hip dislocation. In the teenage years, motor vehicle collisions predominate as the cause of hip dislocations.

\subsection*{Hip and Femur Fractures}

The vast majority of pediatric hip fractures result from high-energy violent trauma. These fractures usually are the result of falling from heights, jumping out of a swing, being struck by a car, or a bicycle accident. Nonaccidental trauma also must be considered. Whereas a car commonly strikes an adult pedestrian at the tibial level, a smaller child most often is hit at the level of the hip, which results in a fracture there.

The Salter-Harris classification of fractures in the pediatric population is not used for hip fractures. The Delbet classification is a well-accepted system used for pediatric femoral fractures.\textsuperscript{84} This system separates fractures through the physis and the transcervical, cervicotrochanteric, and intertrochanteric regions (Fig. 53-32).

\subsection*{Spiral Shaft Fractures}

If seemingly trivial trauma has resulted in a spiral femoral shaft fracture in a child, nonaccidental trauma and pathologic frac-
A pediatric orthopedist is recommended.84 With pediatric femoral fractures. For these reasons, referral to limb length discrepancy all are complications frequently seen fractures. Premature closure of the physeal plate results in a is prevention of the many complications common with femoral allows more treatment options. The primary goal in children bilateralization. Unlike adults, children tolerate bedrest well, which aim at prevention of the complications of prolonged immo-

duration must be considered.85,86 Common causes of pathologic fracture include unicameral bone cysts, fibrous dysplasia, osteogenesis imperfecta, and malignancy.86,87

Management. Femur fractures in children are so rare that most orthopedists treat only three or four in a career.84 Although these pediatric injuries are extremely rare, their complications are significant. Unlike in an adult, a child’s femur has growth potential, and any disruption carries the possibility of lifetime disability. Treatment of femoral shaft fractures in adults is aimed at prevention of the complications of prolonged immobilization. Unlike adults, children tolerate bedrest well, which allows more treatment options. The primary goal in children is prevention of the many complications common with femoral fractures. Premature closure of the physeal plate results in a valgus deformity of the hip. AVN, malunion, nonunion, and limb length discrepancy all are complications frequently seen with pediatric femoral fractures. For these reasons, referral to a pediatric orthopedist is recommended.84

The Child with a Limp

A child who comes to the ED with a limp presents a diagnostic challenge. Both life-threatening and benign disease processes can produce a limp. When the child is too young to give an adequate history, the etiology becomes more elusive. The attending physician should inquire about the chronology of the symptoms, the child’s development (i.e., social milestones, weight gain, physical development), and diet. Associated illness and a family history may be helpful. Although identifying a specific causative disorder is challenging, the history and physical examination, combined with appropriate diagnostic modalities, will allow definitive diagnosis in most patients. An important point is that in the pediatric population, the knee is a common site for referred hip pain. Proper follow-up care is crucial to avoid additional morbidity in these children.

Evaluation of the Child’s Gait

Gait is a learned, complex combination of motions produced through coordination of the musculoskeletal, peripheral, and central nervous systems. A limp is produced by anything that alters this process; the numerous clinical entities that may be associated with a limp can be divided into categories according to the underlying abnormality. Pain, muscle weakness, structural alteration, peripheral sensory deficit, and cerebellar or vestibular imbalance are major categories. A limp caused by pain is referred to as an “antalgic” gait. Conditions that disturb the biomechanics of the hip or cause the child pain may affect any of the elements of gait. Other conditions such as cerebellar pathology or disease of the knee or foot are discussed in their respective chapters.

Etiology of the Limp

Inflammation and Infection

Inflammation of the articular surface, the intra-articular synovium, or the joint capsule creates pain. Weightbearing increases the pain. The child limps in an attempt to limit the time during which the affected hip bears the body’s weight.

Toxic synovitis is a common nonbacterial inflammatory clinical entity that can cause a limp. Little is known about its etiology. It develops most frequently in boys between 3 and 10 years of age. Clinically, the synovitis is manifested as pain in the hip or knee. An antalgic gait is present, with minimal systemic symptoms. There is restriction of hip motion and associated muscle spasm, and the child often will refuse to bear weight on the hip. As the disease progresses, the joint capsule is increasingly stretched, and intra-articular pressure rises. The potential volume of the joint capsule is largest with the hip flexed, abducted, and externally rotated. The child prefers to lie in this position as the capsule begins to bulge, to minimize the tension and intra-articular pressure.

The diagnosis of toxic synovitis must be one of exclusion of more serious diseases that mimic this condition. Acute joint inflammation and pain may be associated with juvenile rheumatic arthritis, systemic lupus erythematosus, Perthes’ disease, septic arthritis, and tuberculous arthritis. Ultrasound imaging of the hip joint will detect an effusion in 78% of cases of toxic synovitis but cannot distinguish this condition from septic arthritis.90 Joint aspiration may be required when the diagnosis is in doubt.

Distinguishing between toxic synovitis and septic arthritis can be a diagnostic dilemma. Recent work has illustrated four key predictors: temperature higher than 38.5°C in the preceding week, non-weight-bearing (refusal or inability to bear weight even with support), erythrocyte sedimentation rate higher than 40 mm/hour, and a white blood cell count greater than 12,000/mL. These four predictors were developed in a retrospective study and then validated in a prospective study.90,99 Based on the validation study, the probability of septic arthritis was 2% for zero predictors, 9.5% for one predictor, 35% for two predictors, 73% for three predictors, and 93% for four predictors.

The use of C-reactive protein (CRP) assay is becoming more prevalent in the evaluation of septic arthritis. Levine and coworkers studied the test characteristics of CRP in septic arthritis and determined the likelihood ratio for a CRP value greater than 10.5 mg/dL to be 2.75 and for a value less than 0.9 mg/dL to be 0.36.10 When CRP evaluation (positive result defined as a value greater than 2.0 mg/dL) was added to the aforementioned four predictors, the probability of septic arthritis was 97.5% when all five were present; however, when all

Figure 53-32. Pediatric proximal femoral fractures are classified by a system that separates fractures in the physis (A), the transcervical area (B), the cervicotrochanteric area (C), and the intertrochanteric region (D). (From Canale ST, Beatty JH: Fractures of the pelvis. In Rockwood JC Jr, Green DP, Bucholz RW [eds]: Rockwood and Green’s Fractures in Children, vol 3, 5th ed. Philadelphia, JB Lippincott, 2001, pp 883–911.)
of the predictors were absent, the probability was still 16.9%.93 Taken together, all of these predictors should be used in conjunction with clinical assessment.

Acute bacterial infections of the hip and femur require early identification and intervention to minimize subsequent morbidity and disability.91 Unfortunately, the diagnosis often is missed initially because the child may appear relatively nontoxic in the early phases of infection. Signs and symptoms of systemic illness usually accompany infection of the femur or hip. Fever, malaise, decreased oral intake, a limp, and refusal to bear any weight are common.94 Whereas osteomyelitis most commonly develops in the metaphysis in adults, the physeal region often is the infected site in children. Pyarthrosis (septic arthritis) may result from hematogenous seeding or direct extension of osteomyelitis. The hip and the knee are the most commonly infected joints.

The causative agent in osteomyelitis and pyarthrosis is nearly always a gram-positive organism, usually *Staphylococcus*. The incidence of *Haemophilus influenzae* infection has fallen as a direct result of addition of the relevant vaccine to the childhood immunization regimen. Neonates, asplenic children, and children with sickle cell anemia are at risk for infection with gram-negative organisms. *Salmonella* infection also is more often seen in patients with sickle cell disease–related osteomyelitis. Viral and rickettsial diseases (e.g., Lyme disease) have been known to be present in subacute cases.

Identification of acute osteomyelitis on plain radiographs is difficult until 2 to 3 weeks after onset of infection. Pyarthrosis may be manifested by widening of the space between the femoral head and the acetabular roof and bulging of the joint capsule and surrounding soft tissues. This is seen as a change in the contour of the gluteus minimus and iliopsoas fat stripes (Fig. 53-33). Care should be taken to identify the normal shadow of the muscles and the joint capsule, as described earlier in this chapter (see Fig. 53-11). Plain radiographs are seldom useful in the initial identification of infection because visualization of a joint effusion has low sensitivity for pyarthrosis. Bone scan, MRI, CT, and ultrasound-guided joint aspiration are appropriate to diagnose a septic joint.

The inflammatory process involved in the immune system’s attempt to eradicate the intruder also begins to destroy the body’s own articular surfaces. Even with treatment, most children experience some arthritic disability. 

**Slipped Capital Femoral Epiphysis**

**Anatomy.** The capital femoral epiphysis appears during the first year of life. The epiphysis of the greater trochanter appears by the age of 5 years and that of the lesser trochanter during the 13th year of life. All of these structures unite between the ages of 17 and 19 years. The anatomic relationship has been compared with a scoop of ice cream sitting on a cone. This relationship remains symmetrical on both anteroposterior and frogleg lateral radiographs (Fig. 53-34A and B). Asymmetry in any view represents either SCFE or a subcapital fracture (Fig. 53-35).

**Epidemiology and Pathophysiology.** SCFE is the most common hip disorder in adolescents, with an incidence of approximately 5 per 100,000 population per year. From 25 to 50% of the cases are bilateral,95,96 SCFE occurs twice as frequently in boys as in girls, with the respective peaks of incidence at the ages of 13 and 11 years.

Epidemiologic data have provided clues to the pathophysiology of this injury. SCFE is associated with the onset of puberty and is rare before the age of 10 years. It is most commonly seen boys 10 to 17 years of age during their period of rapid growth. It is believed to be the result of a structural weakness in physseal cartilage associated with pubescence.96

The specific cause of SCFE is not well understood, and most cases are idiopathic. SCFE occurs more frequently in male African Americans than in the white population, lending support to the presence of a genetic element in the pathophysiology of the condition.96 Other risk factors identified are obesity, previous irradiation or chemotherapy, renal osteodystrophy, hypothyroidism, and neglected septic arthritis.97

**Clinical Features.** SCFE usually is an insidious process extending over a period of several weeks to months. Initially, the only complaint may be slight discomfort in the groin, thigh, or knee after activity. Shear stress combined with a weaker physeal plate leads to slippage of the epiphysis inferiorly and posteriorly in the direction of weight-bearing force. Pain worsens as slippage progresses, and eventually pain may occur at rest as well. Referred pain to the knee is a classic manifestation, and patients frequently present with groin, thigh, or knee pain rather than hip pain. This presentation often causes delay in diagnosis, potentially increasing displacement, and a worsened prognosis.98 Parents often bring the child in for medical evalu-
ation when they notice the child beginning to limp. Physical examination may reveal hip tenderness, decreased hip range of motion, and an abducted, externally rotated thigh.

**Diagnostic Strategies and Treatment.** Children with unexplained hip or knee pain merit clinical as well as radiographic evaluation. Initially, anteroposterior, lateral, and frogleg lateral radiographs of the hip should be obtained. The frogleg lateral projection shows the hip in a plane midway between the anteroposterior and lateral views. The earliest radiographic findings are subtle, with the abnormality visualized on only one projection. The most reliable initial finding with SCFE is asymmetry of the femoral epiphysis in relation to the neck. Small amounts of slippage can be detected by examining the epiphyseal edge as it becomes flush with the superior border of the femoral neck. This can be visualized as “the scoop slipping off the ice cream cone.” The dome of the epiphysis may be flattened. On the radiograph, a line drawn along the superior margin of the femoral neck (Klein’s line) should intersect some part of the normal femoral head. Failure of this line to intersect the head indicates medial and posterior movement of the head on the epiphysis. Comparative views of the two hips are indicated if initial radiographic findings are equivocal. If occult fracture is suspected, MRI or CT should be performed. The goal of treatment is to prevent further slippage and subsequent injury to the physis. The patient should be made non-weight-bearing and referred for orthopedic management. Surgery is required to anchor the epiphysis and prevent further slippage.

**Perthes’ Disease**

Perthes’ disease is the name given to AVN of the pediatric femoral head (Fig. 53-36). It also has been called Legg-Calvé-Perthes disease and Calvé-Perthes disease. It occurs at a younger age than SCFE does. A majority of cases are diagnosed between the ages 4 and 8, with the peak incidence at 6 years. It occurs five times more often in boys than in girls and affects both hips 15 to 24% of the time.

Patients classically present with unilateral, oftentimes painless limp of insidious onset. As the disease progresses, pain becomes nearly constant and typically is exacerbated with activity and exercise. Treatment is controversial and determined by progression of disease and age at diagnosis.

**Isolated Fracture of the Greater or Lesser Trochanter in Children**

An isolated fracture of the greater trochanter is a rare injury. In children, this fracture occurs when the entire greater trochanteric epiphysis is avulsed from the femur. Children and adolescents between 7 and 17 years of age are most commonly affected. The mechanism of injury generally is a powerful
muscular contraction of the lateral rotators of the hip joint during a twisting fall. If the fragment is large and displaced by more than 1 cm, open reduction and internal fixation may be indicated.

An isolated fracture of the lesser trochanter occurs when a forceful contraction of the iliopsoas muscle avulses the lesser trochanter from the physis during sudden hip flexion (Fig. 53-37). Eighty-five percent of all cases occur in patients younger than 20 years, with a peak incidence between the ages of 12 and 16 years. \(^\text{101}\) Marked tenderness can be elicited in the femoral triangle, and hip flexion against resistance is painful. Clinically, the seated patient is unable to lift the foot of the affected leg from the floor. Treatment of an isolated lesser trochanter avulsion fracture usually involves bedrest and early mobilization. Painless active hip motion is achieved within 3 weeks.

Figure 53-37. Forceful contraction of the iliopsoas muscle results in avulsion of the lesser trochanter. (From Kocher MS, Tucker R: Pediatric athletic hip disorders. Clin Sports Med 25:241, 2006.)

KEY CONCEPTS

- **Hip dislocation:** Hip dislocation constitutes one of the few orthopedic emergencies. The likelihood of its complication, AVN, is related to both the initial degree of trauma and the amount of time the femoral head remains out of joint. Reduction of the hip within 6 to 12 hours after dislocation significantly decreases the incidence of AVN. The only true contraindication to hip reduction is the presence of an ipsilateral femoral neck fracture.

- **Hip fracture:** When a painful hip makes ambulation difficult and plain radiographs do not reveal a fracture, MRI should be performed.

- **Intertrochanteric fracture:** Hemodynamic instability may result from dehydration and blood loss of up to 3 units into the fracture site. Up to 70% of patients with these injuries are under-resuscitated.

- **Acetabular fracture:** It is important to identify acetabular fractures before closed reduction is attempted because intra-articular bone fragments may interfere with effective reduction.

- **Slipped capital femoral epiphysis:** This condition is most commonly seen in African American boys 10 to 17 years of age; 25% of cases are bilateral. The most reliable initial finding with SCFE is asymmetry of the femoral epiphysis in relation to the neck, wherein small amounts of slippage give the appearance of “the scoop slipping off the ice cream cone.”

KNEE

PERSPECTIVE

More than 1 million patients presenting with acute knee injuries are seen annually in North American emergency departments (EDs). These injuries range in severity from minor contusions to limb-threatening injuries to the popliteal artery. The knee joins the longest mechanical levers in the body, the femur and tibia, and is thus subject to high forces. It is the largest and most complex joint in the body that functions through a complicated interaction of flexion, extension, rotation, gliding, and rolling. Its large synovial space frequently is involved in infections and other inflammatory conditions.

The main goal in emergency evaluation of the traumatized knee is to prevent further damage by identifying reparable vascular injuries, reducing dislocations, stabilizing fractures, and administering antibiotics when indicated. Definitive treatment of less urgent problems is deferred to other settings, such as primary care offices for chronic knee pain and orthopedic clinics for ligamentous injuries.

PRINCIPLES OF DISEASE: ANATOMY AND PATHOPHYSIOLOGY

The knee is a modified-hinge diarthrodial synovial joint that consists of the tibiofemoral and patellofemoral joints. The head of the fibula, although not part of this articulation, is closely approximated laterally and provides a site for the attachment of muscles and ligaments. Joint stability is provided by ligaments, although surrounding muscles and the joint capsule contribute as well (Fig. 54-1).

The distal femur terminates in the medial and lateral condyles. The femoral condyles protrude anteriorly, leaving a vertical groove between them. Together, these condyles with their groove form the femoral trochlea—trochlea being the term for an anatomic structure that resembles a pulley. The patella slides up and down in the groove during knee extension and flexion. Poor patellar tracking results in lateral subluxation of the patella, causing patellofemoral pain syndrome (discussed later on in greater detail), the most common cause of knee pain in young adults.

The femoral condyles articulate with the superior surface of the tibia and the tibial condyles. Within the joint, medial and lateral menisci are interposed between the femoral and tibial condyles, where they prevent damage to the articular cartilage from friction and impact.

The tibia is anchored to the femur by four strong ligaments, the anterior and posterior cruciate ligaments (ACL and PCL, respectively) and the medial and lateral collateral ligaments (MCL and LCL). The ACL and PCL are located deep within the knee. The ACL arises from the posterior aspect of the femoral intercondylar notch and inserts on the anterior surface of the tibial plateau within the tibial intercondylar notch. It prevents anterior displacement of the tibia relative to the femur. The PCL arises from the anterior aspect of the femoral intercondylar notch and inserts on the posterior surface of the tibial plateau within the tibial intercondylar notch. It prevents posterior displacement of the tibia relative to the femur. The cruciate ligaments have a rich blood supply, and injury typically results in a hemorrhagic knee effusion.

The MCL and the LCL connect the femoral epicondyles to the tibial condyle and the head of the fibula, respectively. The MCL prevents valgus deviation. Valgus deviation refers to abnormal lateral flexion of the tibia relative to the femur when the leg is straight—that is, hinging of the right tibia to the right or hinging of the left tibia to the left. The LCL prevents varus deviation, which is abnormal medial flexion of the tibia relative to the femur.

Functionally the knee joint can be divided into three compartments: patellofemoral, medial tibiofemoral, and lateral tibiofemoral. These compartments, defined anatomically by the articulation of the bones, are contained within the same joint capsule. The patellofemoral compartment, located anteriorly, contains the quadriceps tendon, which envelops the patella, continues inferiorly as the patellar tendon, and terminates on the tibial tubercle. The fibers of the medial and lateral retinacula are found on either side of the patella, originating from the vastus medialis and vastus lateralis. The patella increases the mechanical advantage of the quadriceps tendon. The quadriceps tendon is a continuation of the quadriceps femoris muscle, which consists of the rectus femoris, vastus medialis, vastus lateralis, and vastus intermedius, comprising the important extensor structures of the knee.

The medial tibiofemoral compartment is located on the medial aspect of the knee and consists of the medial femoral condyle, concave medial tibial condyle (plateau), medial meniscus, MCL, adductor tubercle, and pes anserinus. The pes anserinus (literally, “goose foot”) is a three-pronged tendinous structure that is the conjoined insertion of the sartorius, semitendinosus, and gracilis muscles.

The lateral tibiofemoral compartment encompasses the lateral half of the knee joint and includes the lateral femoral...
condyle and epicondyle, lateral tibial condyle (plateau), LCL, lateral meniscus, and popliteus tendon. The fibular head can be palpated posterolaterally and inferiorly to the joint line but is not usually considered a structure of the lateral tibiofemoral compartment.

The knee is surrounded by a thick ligamentous sheath composed largely of tendons and their expansions. The capsule of the knee joint is reinforced at multiple sites: anteriorly, by the ligamentum patellae; medially and laterally, by the medial and lateral patellar retinacula; and posterolaterally, by a combination of structures referred to as the posterolateral corner. The posterolateral corner includes the IT band, biceps femoris, fibular collateral ligament, popliteus complex (tendon, tibial attachment, popliteofibular ligament, lateral meniscal attachments), arcuate complex, fabellofibular ligament, capsular ligament, and joint capsule. The popliteofibular ligament has been identified as an important contributor to posterolateral stability. The synovial capsule of the knee works in unison with the ligamentous structures in strengthening the knee. The tibiofemoral joint communicates with the suprapatellar bursa, which expands in conditions that cause knee effusion. The prepatellar bursa is anterior to the patella and does not communicate with the tibiofemoral joint. It is important not to confuse prepatellar bursitis with a septic knee (i.e., septic arthritis of the tibiofemoral joint).

The popliteal fossa is a rhomboid hollow in the posterior aspect of the knee. It is bounded by the biceps femoris laterally, the semimembranosus and semitendinosus muscles medially, and the two heads of the gastrocnemius muscle inferiorly. Found within the popliteal space are the popliteal artery, the popliteal vein, and the peroneal and tibial nerves. The popliteal artery is found deep within the popliteal fossa and represents the direct continuation of the femoral artery into the popliteal fossa. The popliteal artery is anchored firmly at the proximal and distal ends of the popliteal fossa, which explains the high incidence of arterial injury with knee dislocations. Blood supply to the knee joint comes from the popliteal artery by way of the geniculate arteries. Branches of the geniculate arteries interconnect with other vessels, forming a complex anastomosis around the knee. The circumflex fibular artery is a branch from the anterior tibial artery and constitutes the main blood supply to the head of the fibula.

Blood supply to the head of the fibula is derived in part from two branches of the anterior tibial artery: the anterior and posterior recurrent tibial arteries.

The tibial nerve, along with one of its branches, the common peroneal nerve, is responsible for innervation of the knee. The tibial nerve joins the artery and vein in the popliteal fossa. It is not tethered proximally and seems to be injured less often than the popliteal artery. The common peroneal nerve wraps around the head of the fibula and continues inferiorly as the deep and superficial peroneal nerves. Common peroneal nerve injury may occur in association with injury to the fibula head or may be due to prolonged compression, as when the flexed knee hangs over the edge of a hard surface such as an operating room table. This causes footdrop, in which dorsiflexion strength at the ankle is reduced.

Depending on the population studied, management of knee and leg fractures commonly requires immobilization, which can result in deep vein thrombosis in up to 19% of the cases. Prophylactic treatment with low-molecular-weight heparin can substantially reduce this risk.3

**CLINICAL FEATURES**

**Presentation**

Patients with knee injuries present with pain, tenderness, deformity, limited range of motion, effusion, warmth, or redness. Knee pain without an immediately apparent knee abnormality should prompt a careful evaluation of the entire femur and hip, injuries of which frequently manifest with pain referred to the knee. Patients with radiculopathy of the third, fourth, or fifth lumbar roots also may complain of knee pain. Children with slipped capital femoral epiphysis, toxic tenosynovitis, or septic hip frequently complain of knee pain.

A knee effusion may result from infection, hemarthrosis, lipohemarthrosis, or inflammatory arthritis, and arthrocentesis is commonly required for diagnosis.

High-energy trauma without knee swelling should raise suspicion for disruption of the joint capsule with expulsion of joint fluid and hemorrhage into the thigh or lower leg. Lower-energy injuries are more commonly associated with meniscal tears, patella dislocations, and less severe ligament injuries; in particular, activities with twisting and turning are associated with anterior cruciate and meniscal tears. Immediate deformity, hemarthrosis, or instability suggests intra-articular frac-
Assess neurovascular integrity of the foot.
2. Determine whether a knee effusion is present, and assess for gross deformity.
3. Identify signs of infection (redness, warmth, and effusion out of proportion to mechanism of injury).
4. Localize tenderness.
5. Assess range of motion and perform stability testing and meniscal evaluation when feasible.

Figure 54-2. Sites for palpation of tenderness in the knee: 1, quadriceps tendinitis; 2, prepatellar bursitis, patella pain; 3, retinacular pain after patella subluxation; 4, patella tendinitis; 5, fat pad tenderness; 6, tibial tubercle pain due to Osgood-Schlatter disease; 7, meniscus pain; 8, collateral ligament pain; 9, pes anserine tendinitis-bursitis. (Adapted from Cailliet R: Knee pain. In Soft Tissue Pain and Disability, 3rd ed. Philadelphia, FA Davis, 1976, p 411.)

Physical Examination

Proper examination of the knee requires the patient to be supine with both legs exposed. The evaluation should begin with an assessment of the neurovascular integrity of the foot. The question of whether knee pain may be the result of hip or spine pathology should be raised early. Examination of the knee begins with visual inspection (Box 54-1), followed by palpation (Fig. 54-2). Any obvious deformity, swelling, effusion, or ecchymosis is noted. Localized swelling must be distinguished from the presence of a joint effusion, which may obliterate the normal contour of the knee. If a large effusion is present, the patella is elevated from the femur by fluid, and the patella can be “ballotted” against the femur. Loss of the medial peripatellar concavity may be the only sign of a small knee effusion. A small knee effusion may be accentuated by milking the suprapatellar pouch inferiorly to force fluid into the knee joint. An effusion in the prepatellar bursa is found just beneath the skin anterior to the patella; this should not be confused with a knee effusion.

Palpation for areas of tenderness is performed last because eliciting pain early in the examination may cause the patient to refrain from cooperating fully. The patella and the extensor mechanism should be palpated with attention to the superior pole. In the absence of trauma, tenderness localized here is consistent with quadriceps tendinitis. warmth, erythema, and swelling over the anterior patella may result from prepatellar bursitis. Tenderness along the inferior pole of the patella is seen with peripatellar tendinitis. The insertion of the patellar tendon onto the tibial tubercle should be palpated. Pain at this location in an adolescent is the hallmark of Osgood-Schlatter disease. In an adolescent, pain along the femoral or tibial epiphysis after trauma may represent a Salter-Harris type I fracture (i.e., a nondisplaced fracture through the physis). The joint line should be palpated carefully. Pain along the joint line may indicate meniscal pathology. The posterior aspect of the knee should be examined for fullness, which may indicate a Baker’s cyst, or popliteal artery pseudoaneurysm. Tenderness over the medial or lateral heads of the gastrocnemius may indicate tendinitis or muscle strain.

Accurate diagnosis of soft tissue knee injuries often is impossible in the acute phase because of pain and swelling. In the acute setting, the main goals are to relieve pain, stabilize the joint, rule out vascular injury, and determine the need for radiography. In the subacute setting, range of motion should be assessed. The normal range is from slight hyperextension to approximately 135 degrees of flexion, but the patient’s unaffected knee should be used for comparison. With knee flexion, it is normal for the tibia to glide posteriorly as much as a few millimeters and to rotate internally up to 40 degrees. Similarly, the tibia moves anteriorly and rotates externally during extension. In the extended position, tautness of the ligaments prevents rotary motion. Loss of active extension of the knee and inability to maintain the passively extended knee against gravity are the hallmarks of quadriceps and patellar tendon rupture, which otherwise may be clinically occult.

Tests for Specific Injuries and Disturbances

Stability Testing

Although range of motion is important for documentation of disability, it is stability testing that provides the most specific
diagnostic information. Stability testing seeks to identify tears of the four major ligaments of the knee—ACL, PCL, MCL, and LCL. Results of stability testing often are inaccurate in the acute phase, owing to splinting and effusion, and such testing may be deferred to the subacute setting. When the acute phase has passed, the goal of stability testing is to determine whether a patient may benefit from orthopedic referral for surgical diagnosis and repair.

Anterior Drawer Test

The anterior drawer test seeks to identify tears of the ACL. A positive test result is defined as greater anterior movement of the tibia as compared with the other knee. The test is performed with the patient in a supine position, the hip flexed at 45 degrees, and the knee flexed at 90 degrees. The examiner may stabilize the patient’s tibia by sitting on the patient’s foot. The examiner then determines the amount of step-off between the femoral condyle and the tibial plateau by placing the thumbs over the joint line while exerting a smooth, gentle pull anteriorly on the tibia. The amount of forward displacement is compared with that on the normal side. Significant laxity relative to the contralateral knee is fairly specific for ACL disruption, although a false-positive result can be caused by PCL insufficiency, which allows the tibia to slip back on the femur, showing an abnormal amount of displacement when pulled forward. The test is not sensitive, with only 10% sensitivity in the acute phase, rising to 50% when performed with the patient under general anesthesia. False-negative findings may be due to an effusion preventing knee flexion to 90 degrees, insufficient force applied during the test, or simply the strength of the knee flexors and extensors preventing abnormal movement.

Lachman’s Test

Lachman’s test is the most accurate physical test for anterior cruciate ligament damage, with a sensitivity of 80% when performed acutely and 100% when performed with the patient under general anesthesia. Lachman’s test is done with the knee flexed 20 to 30 degrees while the examiner uses one hand to grasp the thigh and stabilize it. The tibia is pulled forward with an anteriorly directed force, and the examiner notes tibial excursion. The examiner records “firmness” or a “soft endpoint.” The endpoint can be graded as 1+ (0 to 5 mm more displacement than on the normal side), 2+ (5 to 10 mm), or 3+ (greater than 10 mm). The knee should be in a neutral position before manipulation, and the PCL must be intact for the test results to be valid. In an acute injury, any difference in translation or the feeling of a soft or indistinct endpoint may indicate a ligament tear. A PCL injury results in a false-positive test result as the knee is pulled forward. Potential causes of false-negative test results include hamstrings that are very strong or in spasm, meniscal tears, and third-degree MCL tears with posterior medial extension. Specific limitations of Lachman’s test include difficulty quantitating the amount of anterior translation and inability to limit motion of the femur. In addition, the detection of partial tears of the ACL is problematic and less reliable. Lachman’s test also may be difficult to perform if the examiner’s hands are small relative to the patient’s thigh.

Posterior Drawer Test

The posterior drawer test assesses for PCL injury. The posterior drawer test can be accomplished with the patient’s knee flexed at 90 degrees and the foot stabilized by the examiner’s thigh. A smooth backward force is applied to the tibia. Posterior displacement of the tibia more than 5 mm, or a “soft endpoint,” indicates injury to the posterior cruciate ligament. A normal knee should exhibit no significant posterior excursion. The posterior drawer test result may be positive in only 85% of patients with PCL insufficiency documented operatively.

Posterior Sag Sign Test

The posterior sag sign test is a second method of determining PCL integrity. Sensitivity in the acute phase is 79%. The test is done as follows. The patient is placed in a supine position, and a pillow is placed under the distal thigh for support while the heel rests on the stretcher. The knee is flexed to either 45 or 90 degrees, depending on which position provides the greater muscle relaxation. If the tibia sags backward, the test result is considered to be positive, indicating PCL insufficiency. If the posterior sag sign is not appreciated before the different drawer tests are performed, a false-positive result on the anterior drawer test is misinterpreted as an ACL injury. Posterior sag also may be shown by passive elevation of the leg in a fully extended position, with the examiner applying the elevating force at the ankle. As the leg is elevated, the tibia may fall back on the femur if the PCL is ruptured.

Pivot Shift Test

The pivot shift test, also called subluxation provocation or the “jerk” test, is performed to detect anterolateral rotatory instability associated with an injury to the ACL or lateral capsular structure. This test must be done carefully, if at all, in the acutely injured knee because the test maneuvers can exacerbate the initial injury. Sensitivity in the acute phase is only 27%, but the test is highly specific for ACL tear.

The pivot shift test is performed with the patient supine. The knee is examined in full extension. The tibia is internally rotated while the examiner grasps the foot with one hand and applies a mild valgus stress at the level of the knee joint with the other hand. Then, with flexion of the knee to approximately 20 to 30 degrees, a jerk is suddenly felt by the examiner at the anterolateral corner of the proximal tibia. With a positive result, the tibia subluxates when the knee is extended and relocates when it is flexed to 20 to 30 degrees. Grading of the relocation event is as follows: absent (0), rolling (1+), moderate (2+), or momentary locking (3+). Because of pain or spasm, the pivot shift test is unreliable without use of anesthesia.

Instrument Testing

Arthrometers are devices that quantitate anterior displacement of the tibia relative to the femur and are far more accurate in diagnosing ACL tears than the anterior drawer and Lachman’s tests, although these devices are rarely used in the ED setting. Studies using commercially available arthrometers indicate that a side-to-side difference exceeding 3 mm anterior displacement at 20 pounds is predictive of ACL injury with high accuracy.

Collateral Ligament Stress Test

The collateral ligament stress test is used to test the integrity of the MCL and LCL. With the patient lying supine, the examiner applies varus and valgus stress with the knee at 0 and 30 degrees of flexion. Joint line opening is the amount of movement (i.e., hinging) produced between the tibia and the femur; this can be palpated and estimated in millimeters. The normal knee should be subjected to the same amount of valgus and varus stress and joint line opening and then compared with
that in the injured knee. Isolated collateral ligament tears are
detected only with the knee in slight flexion, because in exten-
sion, the cruciate ligaments, capsule, and lesser ligaments of
the knee provide significant lateral stability. Laxity in full
extension implies complete collateral ligament tear and also
injury to the cruciate ligaments or other structures. Laxity may
be graded as follows: grade I, some laxity; grade II, marked
laxity; and grade III, total laxity.

Assessing for Meniscal Tears

Meniscal tears are difficult to diagnose in the acute setting,
and these assessments are best reserved for the convalescent
phase. Even then, small meniscal tears can cause significant
symptoms but may not be detected on physical exam, and
MRI or arthroscopic evaluation may be required for diagnosis.
However, meniscal tears are likely to limit activity, rather than
leading to further damage, so there is less urgency. By contrast,
failure to diagnose a nondisplaced fracture can lead to dis-
placement and severe consequences.

McMurray’s Test

McMurray’s test is used to help identify meniscal tears. The
patient is placed in supine position with the knee hyperflexed.
The examiner grasps the foot with one hand and the injured
knee with the other. The examiner flexes and extends the
knee while simultaneously internally and externally rotating
the tibia on the femur and providing slight varus and valgus
stress. A positive test result is the occurrence of clicking pal-
pable along the joint line, or locking of the knee. Internal
rotation of the leg tests the posterior segment of the lateral
meniscus. External rotation tests the posterior segment of the
medial meniscus. In the acute setting, limitation of range of
motion may not allow sufficient hyperflexion to perform
McMurray’s test, and the test may be falsely negative.

Apley’s Test

Apley’s test also aids in diagnosing meniscal tears. With the
patient prone, the knee is flexed 90 degrees, and the leg is
internally and externally rotated with pressure applied to the
heel. Pain elicited by downward pressure suggests meniscal
pathology. The pain should be relieved with distraction of
the knee and rotation of the leg back to a neutral position. Although
relatively specific, the Apley test has a low sensitivity for
detecting meniscal tears.6

DIAGNOSTIC STRATEGIES

Radiologic Evaluation

Plain Radiographs

In acute knee trauma, the goal of radiography is to rule out
fracture. Radiographs are not 100% sensitive, however, and
sometimes severe symptoms or physical findings suggest the
need for CT or MRI to rule out fracture definitively. One
study found a negative predictive value of only 49% for plain
films in diagnosing knee fracture, with CT as the gold stan-
dard.8 However, all knee and tibial fractures should be managed
with non-weight-bearing instructions, and in the case of sus-
pected fracture with negative plain film, the same approach
may be pursued, with further imaging at a later time, in the
absence of a clinical indication for emergent CT/MRI.

Plain films are useful for diagnosing fracture, effusion, foreign
bodies, joint space narrowing, and lipohemarthrosis. Evaluat-
ing plain films begins with an assessment of bone anatomy and
alignment. Nonobvious fractures are best detected by careful
inspection of the cortex of all visualized bones. Any disruption
of the continuous line of the cortex should raise suspicion for
fracture. Subtle cortical disruptions indicate either nondis-
placed fractures or draining cortical veins. The next step is to
evaluate for the presence of an effusion, seen as a radiolucent
area (of density similar to that of fat) distending the joint
capsule. Presence of a linear interface between two different
densities within an effusion suggests lipohemarthrosis (see Fig.
54-5), in which the effusion contains not only blood but also fat.
This feature results from entry of marrow fat into the joint
cavity and is diagnostic of fracture.

The traditional standard of care was to obtain anteroposte-
rior and lateral radiographic views of the knee in all cases of
acute knee trauma. More recent work has led to validation of
clinical decision rules that help decrease unnecessary radiog-
raphy.9-11 The Ottawa Knee Rule states that radiography is nec-
essary only if any one of five conditions is present: (1) age older
than 55 years, (2) inability to transfer weight from one foot to
the next four times at the time of injury and in the ED, (3)
inability to flex the knee to 90 degrees, (4) patellar tenderness
with no other bone tenderness, or (5) tenderness of the fibular
head. Initial tests found that this rule detected 100% of frac-
tures while allowing significantly fewer radiographs to be
done.10,11 The Pittsburgh Knee Rule similarly was found to be
100% sensitive.12 This decision rule states that radiography is
necessary only if the patient fell or sustained blunt trauma to
the knee, and if either of two conditions is present: (1) age
younger than 12 or older than 50 years or (2) inability to walk
four full weight-bearing steps in the ED.

In a study comparing these two decision rules, both had
good sensitivity, but the Pittsburgh rule was more specific,
allowing fewer radiographs to be done without sacrificing sen-
sitivity; in this study, the sensitivity of the Ottawa rule was
97% (95% confidence interval, 90 to 99%), and the sensitivity
of the Pittsburgh rule was 99% (95% confidence interval, 94
to 100%).13 Either rule may be used, but patients should be
told that this approach is associated with an approximately 1%
chance of a missed fracture and that they should seek reevalu-
ation in the event of persistent or progressive symptoms.

One study validated the Ottawa Knee Rule in children older
than 5 years of age, finding a sensitivity of 100%. The Ottawa
Knee Rule permitted a 31% reduction in the number of radio-
graphic evaluations.14 In another pediatric study, 1 of 13 frac-
tures was missed, implying a sensitivity of only 92%, so
application of the rule in children still requires clinical
judgment.15

In another approach, investigators asked whether a single
lateral radiograph could replace the traditional three-view
“knee series” (anteroposterior, lateral, and tunnel views). These
investigators found that a single lateral view could
detect 100% of fractures identifiable on the full series.16

Joint space narrowing, as seen in osteoarthritis, is easily dis-
cernible on erect standard views. Lateral views may reveal an
abnormally low-riding or high-riding patella. Tangential,
“sunrise,” or “skyline” views are especially good for delineat-
ing the patellofemoral joint. Tangential views are useful to
assess patella tracking or subluxation. Oblique radiographic
studies are used when tibial plateau fractures are suspected
but not seen on routine views, although MRI is far more sensi-
tive. “Tunnel” views, which image the intercondylar notch,
are used to detect tibial spine fractures and loose bodies within
the notch. Although most ligamentous injuries cannot be diag-
nosed by plain radiography, avulsion of the attachment site can
be seen occasionally and provides indirect evidence of liga-
ment disruption. Stress radiographs may aid in the diagnosis
of collateral ligament disruption but generally are not used in
the initial evaluation.
Computed Tomography

Computed tomography (CT) is most useful in detecting and classifying tibial plateau fractures and usually is done when the diagnosis is unclear or if operative intervention is being considered. CT angiography is an excellent tool for detecting injury to the popliteal artery, although its sensitivity relative to traditional angiography has not been quantified. 17

Ultrasound Imaging

Ultrasound imaging is useful in assessing the integrity of ligaments, tendons, and muscles of the knee and can localize and quantify joint effusions. It is particularly useful when MRI is contraindicated. 18 It has gained wide acceptance in the diagnosis of popliteal deep vein thrombosis and Baker’s cyst, which appears as a nonechogenic mass with smooth walls lying medially within the popliteal fossa. The popliteal artery is the most common site for peripheral aneurysms, yet the clinical diagnosis can be difficult. The aneurysm typically occurs just distal to the adductor hiatus in the proximal segment and midsegment of the artery and is bilateral in up to 64% of cases. Coexistent aneurysms of the aorta (reported in 62% of the cases) and femoral artery (in 40%) are common, and screening for these conditions is appropriate. 19

Contrast Arteriography and Color Flow Doppler Studies

Contrast arteriography and color flow Doppler ultrasonography are used to evaluate the arteries of the knee and leg. Traditionally, arteriography was deemed mandatory in all cases of tibiofemoral knee dislocation and in all cases of penetrating trauma in close proximity to major arteries. More recently, serial examination and Doppler scanning have been studied and found to be acceptable alternatives to arteriography in patients with normal findings on distal neurovascular examination. 20 As mentioned previously, CT angiography may replace these modalities. 17

Radionuclide Bone Scan

A radionuclide bone scan can be used to detect osteomyelitis or occult bony injuries, such as stress fractures, osteochondritis dissecans, and avascular necrosis.

Magnetic Resonance Imaging

MRI has replaced contrast arthrography in the workup of occult fractures and ligamentous and meniscal injuries. Contrast arthrography involves injection of radiopaque contrast material into the joint, followed by radiography. Double-contrast arthrography involves injection of both air and contrast. These techniques are rarely performed when MRI is available.

MRI is highly accurate for diagnosis of fractures and ligamentous injuries, although it can miss small meniscal tears. It has proved to be superior to other imaging modalities in the evaluation of osteonecrosis, osteochondritis dissecans, occult fractures, and bone contusion. 21 Its advantages are that it is noninvasive and painless and does not involve exposure to ionizing radiation. MRI of the knee is rarely performed on an emergency basis, because immobilization and non-weight-bearing instructions are always an option, pending outpatient orthopedic evaluation.

Arthroscopy

Arthroscopy of the knee is the most commonly performed orthopedic surgical procedure in the United States. This nonemergent procedure is useful in diagnosis and treatment of knee injuries, including injuries of the meniscus, cruciate ligaments, articular cartilage, capsule, and synovium. The superior diagnostic accuracy of arthroscopy compared with the clinical knee examination has been well documented. In particular, arthroscopy has increased the accuracy of diagnosis of ACL injuries and small capsular tears. It is especially helpful for children, in whom diagnosis can be difficult because developing skeletal changes can obscure pathology. Difficulties in visualization arise when the capsular structures are tight and when meniscal tears are situated posteriorly. Arthroscopy is superior to MRI for diagnosis of meniscal tears and other soft tissue injuries, and the diagnosed problem can be repaired immediately. The need for arthroscopy is established in the convalescent phase of injury and need not be determined in the emergent setting, so long as appropriate referral to an orthopedist is made. 22

Arthrocentesis

Aspiration of fluid from the knee joint can be diagnostic and can reduce pain from a tense effusion. Arthrocentesis should be performed if the injured knee is greatly distended with a tight effusion and when the cause of the joint effusion is unknown. Aspiration of the joint and subsequent analysis can distinguish among simple effusion, hemorrhathrosis, lipohemarthrosis, and septic arthritis. As noted earlier, lipohemarthrosis refers to an effusion containing blood and fat globules and is diagnostic of fracture.

Patient-controlled continuous infusion of various combinations of intra-articular local anesthetics, opiates, tramadol, magnesium, and clonidine has been used with success in reducing postoperative knee pain, although no regimen is clearly superior. 23

KNEE INJURIES

Dislocation

Anatomy and Pathophysiology. True knee dislocation is tibiofemoral dislocation, and this should not be confused with patellofemoral dislocation, a relatively minor injury. Knee dislocation is a limb-threatening emergency, because popliteal artery injury often is present. It requires significant force; two thirds of these injuries result from motor vehicle collisions, with the remainder occurring from falls, sports injuries, and industrial accidents. Knee dislocation is uncommon but should be considered in the setting of an appropriate injury mechanism, because one half of all knee dislocations are reduced before the patient arrives at the ED. 24 Reduction before ED arrival does not lessen the likelihood of vascular injury, and vascular injury should be considered in patients with severe ligamentous injuries and high-energy mechanisms.

Dislocations are always associated with significant ligamentous injury. There is disruption of the joint capsule with accompanying trauma to the muscles and tendons. Vascular injury to the popliteal artery is the most severe complication and is the primary cause of morbidity and limb loss.

The neurovascular bundle, which is composed of the popliteal artery, popliteal vein, and common peroneal nerve, runs posteriorly behind all bony and ligamentous structures in the popliteal fossa. The popliteal artery is fixed in the fibrous tunnel of the adductor magnus hiatus proximally and traverses
the fibrous arch of the soleus and interosseous membrane distally. In essence, it is tethered to the femur and the tibia, and its inherent immobility renders it susceptible to injury during dislocation. Because of the parallel course of the popliteal vein and the peroneal nerve, they are vulnerable to simultaneous injury.

Traumatic dislocation of the knee can be characterized by the mechanism of injury and the type of dislocation. The injury is most commonly sustained in high-velocity accidents, such as motor vehicle and motorcycle collisions, or in severe crush injuries. Anatomically, dislocations are described according to the displacement of the tibia relative to the femur. They are classified into five types: anterior, posterior, medial, lateral, and rotary. More than half of all dislocations are anterior and result from hyperextension. Posterior dislocations are the second most common type and usually result from high-velocity direct trauma to the flexed knee, often in association with vehicular trauma (dashboard-type injury). The remaining dislocations are lateral, medial, or rotary dislocations and result from direct or indirect trauma producing valgus, varus, or rotary forces, respectively.

Clinical Features. The diagnosis of knee dislocation is based on the mechanism of injury and clinical and radiographic findings. Clinical deformity should be easily palpable when a dislocation is present. Swelling may be absent, however, because of the associated tearing of the capsular structures and dissipation of the acute hemorrhage into the adjacent soft tissue. The initial evaluation may not reveal an obvious gross deformity because of the variable occurrence of spontaneous reduction. Some experts have advocated expanding the definition of knee dislocation to include bicornuate ligament (i.e., ACL and PCL) injuries, even when the knee is reduced on initial pre-knee dislocation to include bicruciate ligament injury should be evaluated for concomitant vascular injury.

Evaluation of the limb vascular status is the most important part of the initial physical examination of knee dislocation. All knee dislocations may warrant vascular surgery consultation, but the “hard” signs of vascular injury necessitate immediate surgical consultation. These signs include absence of pulse, limb ischemia, rapidly expanding hematoma, pulsatile bleeding, and bruit or thrill over the wound, especially in penetrating injuries. When popliteal artery repair is delayed, the amputation rate increases with time, nearing 90% after 8 hours. The posterior tibial and dorsal pedal pulses should be evaluated. Doppler pressure measurements and peripheral pulse determinations have high specificity but poor sensitivity, because approximately 10% of popliteal artery injuries are associated with a normal pedal pulse.

Minor vascular injuries, such as isolated intimal tears, are often treated conservatively, but a vascular surgeon should be consulted when possible. Isolated intimal tears are identified by arteriography and undetectable on physical examination. Injuries to small branches of the popliteal artery can be managed by observation and serial examinations. Vigilance is necessary because apparently minor injuries can lead to compartment syndrome.

Neurologic integrity in the limb also should be assessed, because peripheral nerve injury may be associated with all types of dislocation. Peroneal nerve injury is the most common major neurologic problem associated with knee dislocation; some degree of dysfunction occurs in 20 to 40% of patients and is permanent in approximately 80% of these. The peroneal nerve should be evaluated by determining sensation of the dorsum of the foot and by having the patient dorsiflex the ankle. Less commonly, the posterior tibial nerve may be injured, manifesting as diminished plantar sensation and plantar flexion of the foot. Complete nerve palsy in the acute setting has been associated with a poor prognosis for recovery.

Diagnostic Strategies. Radiographic examination usually confirms the clinical findings (Fig. 54-3). In rare posterolateral and rotary dislocations, radiographic interpretation may be more difficult. Radiographic examination also serves to document associated fractures.

Figure 54-3. Anterior dislocation of the knee. A, Anteroposterior view shows overlap of the femur and tibia, which is never seen under normal circumstances. The anteriorly displaced tibia is magnified. B, Lateral view shows anterior displacement of the tibia in relation to the femur. The patella also is anteriorly displaced. (From Rosen P, et al: Diagnostic Radiology in Emergency Medicine. St. Louis, Mosby, 1992, p 194.)
Contrast arteriography has been the standard of care modality for diagnosis of injuries to the popliteal artery. More recently, however, debate has emerged in the trauma literature regarding whether all patients with knee dislocations require arteriography. Some studies have found that serial examinations can detect all clinically significant injuries, whereas others have emphasized the occasional occurrence of an occult arterial injury. Meta-analysis indicates that absence of normal pulses has only 79% sensitivity for a surgical popliteal artery injury after knee dislocation, suggesting that the default strategy should still be to perform angiography in these patients.\(^4,3^{0}\) Color flow Doppler ultrasonography is gaining acceptance as an alternative to arteriography in some treatment centers, but it may not be as readily available during off-hours. Many trauma patients today have CT scans with intravenous contrast, and this is likely to replace angiography after further research.\(^17,31,32\)

**Management.** The dislocated knee should be reduced immediately. For patients being transferred from nontrauma centers to trauma centers, reduction should be attempted before transfer. Reduction usually can be accomplished with simple traction-countertraction, preferably with use of intravenous moderate (“conscious”) sedation; general anesthesia is rarely necessary. Radiographic confirmation is not required before reduction but is desirable if readily available. Neurovascular status should be documented before and after reduction is achieved. The limb should be immobilized in a long leg posterior splint with the knee in 15 to 20 degrees of flexion. Circumferential casting is avoided in the acute setting. When vascular injury is suspected or if immediate exploration is not planned, a Doppler flow ultrasound study, CT angiography, or standard angiography should be considered, in consultation with a vascular surgeon. Current indications for immediate surgery include obvious vascular injury with a cool, cyanotic ischemic lower extremity and irreducible or open dislocations. Arthroscopy is contraindicated in the acute setting because of the risk of fluid extravasation secondary to capsular deficiencies.

Loss and disability are minimized by expedient revascularization and primary arterial repair, heparinization when not contraindicated, repair of popliteal venous injury, aggressive wound débridement, and early soft tissue coverage. In the absence of vascular injury, early operative intervention does seem to confer an advantage.\(^3^{3}\) Four-compartment fasciotomy is recommended by some clinicians, to minimize the consequences of reperfusion edema in patients who undergo vascular repair.

If the neurovascular structures remain intact after dislocation, the knee joint is reduced and allowed to rest for 2 to 3 days before reconstruction of the torn ligaments is considered. In follow-up studies, clinical instability generally is not a problem, but chronic pain and discomfort are present in nearly one half of the patients. Loss of motion is a common complication, and extensive damage to the articular surfaces at the time of injury increases the risk of early osteoarthritis.

Failure to achieve a closed reduction is uncommon. Delayed complications associated with traumatic knee dislocations include deep vein thrombosis, compartment syndrome, pseudoaneurysm, and arterial thrombosis. Compartment syndromes generally develop within 24 to 48 hours of the initial injury. Pseudoaneurysms are rare; they may form several hours to months after popliteal artery injury.\(^24\) Heterotopic ossification is a poorly understood syndrome of calcification of the soft tissues of the knee. It has been observed in uninjured knees of patients who sustained major trauma. In its most severe form, heterotopic ossification can cause dramatic decrease in knee mobility. Almost one half of dislocated knees are found to have subsequent heterotopic ossification, although the most function-limiting form may be limited to patients with a history of severe trauma.\(^3^{5}\)

**Distal Femur Fractures**

**Anatomy and Pathophysiology.** Distal femur fractures are uncommon, comprising approximately 4% of femur fractures.\(^3^{6}\) A high-energy mechanism of injury is required. An isolated fracture of the femoral condyle may occur, or the fracture may extend in a T or Y pattern to include the intercondylar or supracondylar region of the femur. Condylar fractures are intra-articular and may result in disruption of the articular surface with subsequent arthritis.

**Clinical Features.** Patients with condylar or intercondylar fractures have pain and swelling in the distal femur and suprapatellar region and often are unable to bear weight. Examination may reveal shortening, rotation, and angulation of the extremity and tenderness to palpation along the medial or lateral joint line. Acute hemarthrosis is common and may be secondary to intra-articular extension of the fracture or associated ligamentous injury. Careful assessment of the circulation and motor function of the limb should be documented. Any soft tissue defect in the region of the fracture is considered to be an open fracture until proven otherwise. A fracture (or other injury, for that matter) thought to enter the knee joint can be evaluated with methylene blue injection. Using sterile technique, methylene blue is injected into the tibiofemoral joint at a site distant from the skin injury, until the joint is distended. Emergence of methylene blue from the skin lesion confirms an open joint. If methylene blue does not emerge from the skin injury, an open joint is highly unlikely; the methylene blue should be aspirated. Some authorities recommend use of normal saline rather than methylene blue, as the latter can stain cartilage and make arthroscopy difficult.

**Diagnostic Strategies.** The diagnosis of a distal femur fracture is made from radiographs. Routine anteroposterior and lateral views should be obtained and usually show the fracture pattern and any significant displacement of fragments. In high-energy injuries, radiographs of the ipsilateral hip and tibia are required to exclude associated fractures. Occasionally, CT or MRI may be required to diagnose a nondisplaced fracture. MRI is more sensitive, although CT is more readily available. If signs of vascular impairment are present, a vascular study should be obtained promptly when surgical exploration is not being considered.

**Management.** After the initial examination, the leg should be splinted to prevent excessive motion of the fracture site. Early orthopedic consultation is advised. In a stable patient with an uncomplicated fracture, reduction may be done with skeletal traction followed by immobilization. Intra-articular fractures generally are treated with open reduction and internal fixation. Distal femoral fractures may be associated with thrombophlebitis, fat embolus syndrome, delayed union or malunion if reduction is incomplete or not maintained, intra-articular or quadricipes adhesions if the fracture is intra-articular, angulation deformities, and osteoarthritis, particularly affecting the patellofemoral articulation.

**Tibial Plateau Fractures**

**Anatomy and Pathophysiology.** The proximal end of the tibia is expanded into the medial and lateral condyles, the former having the greater surface of the two. Together they make up approximately three quarters of the proximal tibial surface, and their integrity is important for normal knee alignment, stability, and motion. The plateau normally slopes 10 degrees
Tibial plateau fractures often are intra-articular and result in loss of joint congruity. The forces that normally act on the tibial condyles include axial compression and rotation. The most common mechanism of injury is a strong valgus force with axial loading. Severe high-energy tibial plateau fractures occur primarily in younger patients and are often the result of motor vehicle collisions or falls from heights. These fractures occur in concert with many other injuries and may be open. Fatigue stress fractures of the tibial plateau occur mostly in elderly persons. These low-energy fractures are the result of compression forces in osteoporotic bones.

Tibial plateau fractures encompass many differing degrees of articular depression and displacement. Because the initial injury mechanism usually is a valgus stress with an abduction force on the leg, 55 to 70% of condylar fractures involve the lateral plateau. Medial plateau fractures typically result from adduction forces on the distal leg and account for 10 to 23% of these fractures; both plateaus are involved 11 to 31% of the time.38 If the knee is extended at the time of injury, the fracture tends to be anterior. Posterior condylar fractures usually occur when the knee is flexed at the time of impact.

The Segond fracture represents a bone avulsion of the lateral tibial plateau (Fig. 54-4). The avulsion occurs at the site of attachment of the lateral capsular ligament. On radiographs, an oval-shaped fragment can be seen adjacent to the lateral tibial plateau; this injury must be differentiated from an avulsion from the adjacent fibular styloid. The Segond fracture is an important marker of ACL disruption and anterolateral rotatory instability. Most Segond fractures are caused by sports injuries, and the mechanism is almost always knee flexion with excessive internal rotation and varus stress. Segond fractures can be detected on radiographs (lateral capsule sign) or even ultrasound images, but MRI usually is performed in the acute phase to delineate the expected soft tissue disruption.37

Clinical Features. Clinical manifestations of knee fractures are the presence of an effusion, inability to bear weight, severe joint line tenderness, ecchymosis, and localized soft tissue swelling and pain. A common associated finding is acute hemarthrosis with decreased range of motion. Tenderness is present over the fracture but also may be found near torn collateral ligaments. A valgus or varus limb deformity may be present and usually indicates a depressed fracture or concomitant ipsilateral leg fracture. The most important aspect of the initial examination is assessment of neurovascular status. Tibial plateau fractures produce a high percentage of vascular complications. The popliteal artery is immobile in this region and branches into the anterior and posterior tibial arteries at the upper edge of the interosseous membrane. The popliteal artery may be injured by fragments from bicondylar or comminuted fractures involving the subcondylar area. Vascular impairment may result in distal circulatory compromise. Displaced fractures of the lateral condyle may produce peroneal nerve paralysis in addition to injury to the anterior tibial artery. Stretch of the peroneal nerve is the usual cause of injury.

Soft tissue injuries also may involve the capsuloligamentous structures of the knee. Ligamentous injuries accompany tibial plateau fractures in up to 66% of cases, most often involving the ACL and MCL.38 Although ligament injuries can occur with any type of tibial plateau fracture, they occur more commonly with local compression and split compression fractures (see Fig. 54-4).29

Cruciate ligament injuries associated with tibial plateau fractures are associated with an increased incidence of late traumatic arthritis and a poor prognosis. Regardless of the type of treatment, operative or nonoperative, tibial plateau fractures with significant residual laxity fare poorly in comparison with stable fractures.39

Most experts agree that four factors determine the prognosis of tibial plateau fractures: (1) degree of articular depression, (2) extent and separation of the condylar fracture lines, (3) diaphyseal-metaphyseal comminution and dissociation, and (4) integrity of the soft tissue envelope (i.e., open versus closed). Fractures of the tibial plateau generally carry a good prognosis, with good to excellent results reported in 90% of patients more than 20 years after injury; however, high-energy tibial plateau fractures generally are associated with a more guarded prognosis.40 In high-energy fractures, a large degree of articular depression, multiple displaced condylar fracture lines, and diaphyseal-metaphyseal extension and comminution in association with open injuries or an extensive internal degloving injury may occur and are poor prognostic signs.41

Diagnostic Strategies. Lipohemarthrosis, seen as a fat-fluid level on a plain film, suggests an occult fracture and is due to entry of marrow fat into the joint space42 (Fig. 54-5). Lipohemarthrosis also is detected when fat globules are found on aspiration of a hemarthrosis. All knee radiographs should be examined closely for bone avulsion fragments from the fibular head, femoral condyles, and intercondylar eminence, because these may indicate ligamentous injury. Widened joint spaces associated with a fracture of the opposite condyle also may indicate concomitant ligamentous injury.

CT and MRI are more sensitive than plain radiography, help localize occult lesions, and help quantify the amount of depression in displaced fractures and the extent of articular surface involvement in comminuted fractures.43 These studies

Figure 54-4. Anteroposterior view of the left knee shows lateral curvilinear avulsion fracture (arrow) and joint effusion. (From Kerr HD: Segond fracture, hemarthrosis, and anterior cruciate ligament disruption. J Emerg Med 8:29, 1990.)
need not be undertaken emergently, because the knee can be immobilized pending orthopedic consultation. MRI is more sensitive than CT and should be consider the gold standard.

Several classification systems have been proposed. Most such systems depend on the mechanism of injury (i.e., the location and force with which the femoral condyle is driven into the plateau). The revised Hohl classification is in common although not universal use. As shown in Figure 54-6, this system divides the plateau fractures into two categories: minimally displaced (less than 4 mm of depression or displacement) and displaced. Displaced fractures are subdivided into six distinct types: local compression, split compression, total depression, splint, rim, and bicondylar.

Management. All patients with a tibial plateau fracture should be referred for evaluation by an orthopedist. In the acute phase, the fracture should be immobilized in a noncircumferential splint and the patient should not bear weight on the limb until seen by an orthopedist. The therapeutic goals include precise reconstruction of the articular surfaces, stable fragment fixation, and early knee motion to prevent stiffness. Weightbearing generally is delayed until healing is complete, usually 6 to 8 weeks. Stable nondisplaced fractures may be

Figure 54-5. Lipohemarthrosis. A, A lateral plain film of the knee of a young woman with a nondisplaced patella fracture. The only radiographic abnormality is an effusion that contains a linear interface (arrow) between two soft tissue densities, suggesting lipohemarthrosis. B, A magnetic resonance image from the same patient shows plainly the presence of blood and fat in the effusion (arrow) (the nondisplaced patella fracture is not seen).

Figure 54-6. Hohl's revised classification of tibial plateau fractures: minimally displaced (accounting for 22% of such fractures), local compression (28%), split compression (18%), total depression (13%), split (3%), rim avulsion or compression (5%), and bicondylar (11%). (Modified from Watson JT, Wiss AA: Fractures of the proximal tibia and fibula. In Rockwood CA Jr, Green DP [eds]: Fractures, vol 3, 5th ed. Philadelphia, JB Lippincott, 2001.)
treated with immobilization alone, but instability or significant depression or disruption of the joint surface will necessitate surgical management.36

Early complications of tibial plateau fractures include wound infection, loss of reduction, and development of compartment syndrome. Compartment syndromes most commonly occur with high-energy fractures, typically within the first 24 to 48 hours after injury. Deep vein thrombosis also may occur, and prophylactic anticoagulation should be considered in consultation with an orthopedist. The most common late complication is the development of osteoarthritis in the affected compartment.

Fractures of the Intercondylar Eminence (Tibial Spine)

Anatomy and Pathophysiology. The intercondylar eminence, or tibial spine, is the central portion of the proximal tibial surface. The spine has two prominences: the medial and the lateral tubercle. The medial tubercle is larger and located more anteriorly than the lateral tubercle. Two intercondylar fossae are present on the proximal tibial surface, one anterior to the intercondylar eminence and one posterior to it. The ACL and the anterior horns of the medial and the lateral menisci attach in the anterior intercondylar fossa. The PCL and the posterior horns of the menisci attach in the posterior intercondylar fossa.

Tibial spine fractures are commonly seen in children and adolescents, but a study suggests that these fractures occur more frequently in adults than was previously thought.33 The injury is more common in children than in adults because the ligaments are stronger than the adjacent physeal plates in the immature skeleton. A fracture of the anterior tibial spine in children usually is associated with an ACL rupture, as is the case in adults.

Most tibial spine fractures occur as the result of violent knee twisting, hyperflexion, hyperextension, or varus-valgus forces generated during motor vehicle collisions or athletic activities. The tibial spines are fractured by twisting knee movements, whereas hyperextension or hyperflexion forces may cause avulsion of the intercondylar eminence or of the cruciate ligaments from their tibial attachments.

Clinical Features. After tibial spine fracture, the patient complains of pain and swelling of the knee and may be unable to bear weight on the affected extremity. Examination confirms acute hemarthrosis and may reveal a block to full knee extension. Tense effusion may limit range of motion, hinder physical examination, and mask ligament disruption. Definite ACL laxity is associated with this injury, and patients may exhibit an anterior drawer sign, a positive result on Lachman’s test, or peripheral meniscal tears. Type III may be subdivided into type IIIA, fractures with complete displacement, and type IIIB, fractures with displacement and rotation (see Fig. 54-7).

Arthroscopy is useful for diagnosis and treatment of tibial spine fractures. This modality allows drainage of tense hemarthrosis and enables precise diagnosis and classification, especially for children, in whom the diagnosis can be difficult because of developing skeletal changes.

Management. Conservative treatment is effective for all type I injuries. Nondisplaced or incomplete tibial spine fractures generally heal well when treated with cast immobilization in full extension for approximately 6 weeks. Type I and II fractures may require arthroscopy for lavage and accurate classification. If satisfactory closed reduction cannot be obtained or there is associated ligamentous injury, open or arthroscopic reduction and internal fixation should be performed. To restore normal function of the ACL, displaced or rotated fragments must be reduced. Type III fractures usually require arthroscopic or open reduction; screws and tension band wiring techniques have yielded excellent results.36 With most uncomplicated fractures of the tibial spine, a good result can be expected
when the fracture heals and restores function to the avulsed ACL. A poor outcome, with residual pain and instability, may be associated with additional intra-articular fractures and damage to the MCL.

**Epiphyseal Fractures**

**Anatomy and Pathophysiology.** The physes, which occur at the end of the long bones, are primarily responsible for longitudinal growth through the process of endochondral ossification. From birth to skeletal maturity, the distal femoral growth plate contributes 70% of the growth of the femur and 57% of the growth of the lower extremity. Likewise, the upper tibial epiphysis accounts for most of the long growth of the tibia.

Biomechanical data and clinical studies in children and adolescents have confirmed that the ligaments and articular capsule are firmer than the bone and epiphyseal plate. As a result, trauma to this region of the maturing skeleton usually injures the cartilaginous epiphyseal plate. In this way, the physis protects the joint surface from the grossly comminuted fractures seen in adults.

Despite data showing that the physis is the weakest link in the immature skeletal unit, only 15 to 20% of all fractures in children occur through the growth plate. The proximal tibial physis is far more resistant than other physes as a result of the unique anatomic features of this site. The proximal tibial physis has no significant attachments to the collateral ligaments of the knee. The LCL inserts into the head of the fibula and has no tibial attachment, and the MCL has only a minor attachment to the epiphysis. The major portion of this ligament is attached to the tibial shaft well below the epiphysis. Varus or valgus stress is more likely to injure the cartilaginous epiphyseal plate. In this way, the physis protects the joint surface from the grossly comminuted fractures seen in adults.

The proximal tibial physis is far more resistant than other physes as a result of the unique anatomic features of this site. The proximal tibial physis has no significant attachments to the collateral ligaments of the knee. The LCL inserts into the head of the fibula and has no tibial attachment, and the MCL has only a minor attachment to the epiphysis. The major portion of this ligament is attached to the tibial shaft well below the epiphysis. Varus or valgus stress is more likely to injure the distal femoral physis or the tibial metaphysis. Fracture-separation of the distal femoral growth plate and proximal tibial epiphysis most often is caused by an indirect mechanism, commonly related to sports injuries. The Salter-Harris classification of epiphyseal injuries is described in Chapter 46.

**Clinical Features.** Epiphyseal injuries should be suspected in a child or adolescent who has juxta-articular (growth plate) tenderness, limps, or refuses to or cannot bear weight. The degree of discomfort varies, but the pain often is severe. Depending on the mechanism of injury, the overlying soft tissue may be abraded or lacerated. Swelling is usual in the overlying soft tissue, and an effusion may be present. If the separation is displaced, an angular deformity may be noted.

Epiphyseal growth plate fractures in the lower extremity carry a high incidence of associated injury. Physeal fractures in the region of the knee may be associated with ligament injuries, especially to the ACL and MCL, in one half of the patients. The most serious injury associated with a proximal tibial physis fracture is neurovascular trauma. In particular, popliteal artery injuries have been associated with these fractures, especially when posterolateral or posteromedial displacement is a feature. Peroneal nerve injury also has been reported and may range in severity from neurapraxia to complete disruption. Bone bruise is a radiographic diagnosis, involving areas of cancellous bone with high signal intensity on MRI fat suppression sequences. Bone bruise may be present in approximately one half of acutely injured knees. A high proportion of patients with a bone bruise have significant soft tissue injury. Nearly all bone bruises resolve after 1 year.

**Osteochondritis Dissecans**

Osteochondritis dissecans is a rare orthopedic disorder of unknown etiology (Fig. 54-8). The disorder is found mainly in adolescents and results in partial or total separation of a segment of articular cartilage and subchondral bone from the underlying bone. It is commonly unilateral, involving the non-weight-bearing lateral aspect of the medial femoral condyle, and is thought to be related to acute or chronic trauma. Occasionally the lateral femoral condyle or inferior patella pole is involved. Patients often have pain, swelling, and giving-way pain, which may occur during participating in activities such as football or skiing. This pain usually is continuous and may be worse after activity. The condition can be treated conservatively with rest, ice, and physical therapy, or it may require surgical intervention. The outlook for recovery is generally good, with successful resolution in most cases.
episodes without a history of trauma. Localized tenderness of the condyle often is the only physical finding. Routine radiographic views usually are diagnostic: A subcortical lucency (see Fig. 54-8) can be appreciated, and an osteochondral fragment may be seen separated from the underlying bone. MRI or CT may aid in determining the exact location and extent of the osteochondrotic lesion. Emergency department patients with suspected osteochondritis dissecans should be non-weight-bearing until seen by an orthopedist.

The management of these patients is based on the stability of the osteochondral fragment and the maturity of the skeleton. If the epiphyses are open, conservative treatment with protective weightbearing usually results in healing of the lesion. When the epiphyses are closed, surgical healing is guarded. If the fragments are detached, the loose fragments require surgery for removal or fixation. Protected range of motion with non-weight-bearing activity for 6 to 10 weeks generally is advised.

Osteonecrosis

Osteonecrosis occurs when disruption of the blood supply to the bone causes infarction. The knee is a common site of involvement, particularly the weight-bearing surface of the medial femoral condyle. Spontaneous osteonecrosis usually affects middle-aged and elderly patients, whereas secondary osteonecrosis may occur in younger patients related to corticosteroid therapy or in association with sickle cell disease, lupus, or renal transplantation, among many other risk factors. The exact etiology is unknown. A common clinical presentation is spontaneous onset of severe localized knee pain that may be accompanied by an effusion and loss of joint motion. The physical examination reveals point tenderness over the involved femoral condyle or tibial compartment. Radiographs obtained at the onset of symptoms usually are normal in appearance, and the diagnosis is confirmed with technetium bone scanning, which shows increased activity. MRI also is diagnostic of acute osteonecrosis. Subchondral marrow signal abnormality is the earliest change noted; subchondral collapse and fracture may be seen in more advanced cases.

Initially, most patients can be managed with conservative treatment consisting of rest, protected weightbearing, and nonsteroidal anti-inflammatory drugs (NSAIDs). The outcome depends on the percentage of the weight-bearing surface involved with the process. If the lesion is small, no surgical treatment is required. Over the long term, degenerative changes will develop in most patients, but initially the changes are not severe. For more advanced stages of femoral osteonecrosis, various surgical treatments have been proposed, including arthroscopic débridement, proximal tibial osteotomy, prosthetic replacement, and allografting.

Extensor Mechanism Injuries

Anatomy and Pathophysiology. The extensor mechanism consists of the quadriceps muscles, quadriceps tendon, medial and lateral retinacula, patella, patellar tendon, and tibial tubercle (Fig. 54-9). Passive and dynamic stabilization of the patella are aided by the surrounding soft tissue. Although this anatomic complex encompasses the most superficial aspect of the knee, ruptures of the extensor mechanism are infrequent injuries relative to other types of injuries of the knee joint. Disruptions of the extensor mechanism may occur at any level from the quadriceps muscle to the insertion on the tibial tubercle. Injury generally occurs as a result of sudden vigorous contraction of the quadriceps muscle with the knee in a flexed position, laceration, or a direct blow. Rupture of the quadriceps tendon usually occurs at or just proximal to the patellar insertion. Occasionally the rupture may extend into the vastus intermedius tendon or transversely into the retinaculum. Most patellar tendon ruptures occur at the site of origin on the inferior pole of the patella.

Tendons of the extensor mechanism are extremely resistant to tensile loads and do not rupture under normal physiologic conditions, even with significant degrees of stress. Chronic systemic conditions, including rheumatoid arthritis, gout, systemic lupus erythematosus, hyperparathyroidism, and iatrogenic immunosuppression in organ transplant recipients, may render the tendon vulnerable to rupture. Several studies have implicated use of steroids or fluoroquinolones in tendon rupture. Age also seems to be a factor, with quadriceps tendon rupture usually occurring in patients 40 years of age or older and patellar tendon rupture occurring in patients younger than 40. In children, quadriceps and patellar tendon ruptures are rare, and muscle tears seem to predominate. In adolescents, patellofemoral dysplasia, chronic tendinitis, and the use of steroids seem to be predisposing factors. Dysplasia may cause extensor mechanism injury by repetitive tensile overloading, and corticosteroids seem to weaken collagen ultrastructure and impair the reparative process.
**Clinical Features.** Clinical evaluation can elicit the correct diagnosis in most cases of complete disruption of the extensor mechanism. Patients with extensor disruption may have the following signs and symptoms: (1) acute onset of pain, swelling, and ecchymoses over the anterior aspect of the knee and a palpable defect in the patella, quadriceps tendon, or patella tendon; (2) loss or limitation of ability for active leg extension (extension lag usually is seen when the last 10 degrees of extension is performed haltingly or with difficulty); (3) high-riding patella (patella alta) with patellar tendon rupture and superior retraction; and (4) low-riding patella (patella baja) with quadriceps tendon rupture and inferior retraction. Partial disruptions may be difficult to diagnose on clinical examination and may require MRI for confirmation.

**Diagnostic Strategies.** Standard anteroposterior and lateral radiographs should be obtained and may reveal characteristic findings, possibly including obliteration of the quadriceps or patella tendon, a poorly defined suprapatellar or infrapatellar soft tissue mass, soft tissue calcific densities, or a displaced patella (Fig. 54-10). Patella alta may be sought on the lateral radiograph using a ratio of patellar length to patellar tendon length (the Insall-Salvati ratio). If this ratio is less than 0.8, patella alta is present. The degree of flexion should not affect this ratio, which relies on the inelasticity of the patellar tendon. In patients with quadriceps rupture, degenerative spurring of the patella (tooth sign) commonly is seen on tangential views. Obliteration of the extensor tendons may be caused by a frayed tendon and surrounding hematoma. A soft tissue mass represents proximal or distal retraction of the torn tendon. Calcific densities may represent avulsed bone fragments of the patella or tibial tubercle or dystrophic calcifications in the substance of the tendons. Despite these multiple radiographic signs, the correct diagnosis is infrequently made by plain radiography in cases of incomplete quadriceps tendon rupture. MRI shows the entire extensor mechanism and is the best imaging modality for diagnosing pathology in this system, even in the acute phase. MRI usually is reserved for patients with possible incomplete disruption or for those with a complication of intra-articular derangements.

**Management.** Treatment of acute extensor mechanism injuries produces a much better clinical outcome if instituted early, within 2 to 6 weeks of the initial injury. Accurate diagnosis at the time of injury is essential. Patients with delayed diagnosis of patellar tendon rupture may experience significant retraction of the patella proximally and subsequent development of quadriceps contractures or adhesions. If the tear is only partial, immobilization with the knee in full extension for 4 to 6 weeks is the treatment of choice. Surgical intervention is required for reattachment of complete tendon ruptures, and repair should be performed as soon as possible after injury to obtain the best results. Numerous techniques have been described for early and late repairs, and the choice of procedure depends on several factors, including location of the tear, lag time between injury and repair, and presence or absence of adhesions. After primary repair, the knee is immobilized in full extension with a long leg cast until healing is complete. Gradually progressive active and passive range-of-motion exercises are indicated for optimal results.

**Patellar Fractures**

**Anatomy and Pathophysiology.** The patella is the largest sesamoid bone in the body. It is held in place by the quadriceps tendon, the patellar ligament, and the medial and lateral retinacula. As an integral part of the extensor mechanism, the patella increases the effective lever arm of the quadriceps by providing anterior displacement of the quadriceps tendon. All fractures of the patella, except for small avulsion fractures of the rim, are intra-articular.

Patellar fractures constitute approximately 1% of all skeletal injuries and occur in all age groups. Patellar fractures are classified as transverse, stellate, or comminuted; longitudinal or marginal; proximal pole or distal pole; and rarely osteochondral. They may be either displaced or nondisplaced and occur either from direct or indirect forces or from dislocation. The most common fracture pattern is the transverse fracture (accounting for 50 to 80% of cases). This type often is seen in young adults and usually results from a powerful contractile force transmitted from the quadriceps tendon. This force may pull the superior portion of the patella upward, leading to wide displacement. In such cases, the medial and lateral retinacula are usually disrupted, resulting in significant functional dis-
ability; active extension is impossible. Nondisplaced transverse patellar fractures usually are caused by a direct blow to the anterior aspect of the patella (e.g., a fall on the knee or a direct blow sustained in vehicular trauma). The retinaculum and extensor mechanism usually remain intact, and the patient retains limited functional ability for active extension. Stellate and comminuted fractures account for 30 to 35% of all patellar fractures and commonly result from a direct impact. The fracture elements often appear as separated fragments on plain radiographs, but they are held in place and supported by the medial and lateral retinacula and the overlying soft tissues. Small proximal fragments are at risk for avascular necrosis because the patellar blood supply is central and inferior. Longitudinal or marginal vertical patellar fractures are less common, usually are the result of direct injury, and involve the lateral facet.

Clinical Features. On physical examination, tenderness, swelling, and ecchymosis over the patella and prepatellar bursa are noted. Active extension may be limited or absent, depending on the fracture pattern and amount of fragment displacement. Associated injuries may include fractures of the femoral neck, dislocation of the hip, and acetabulum fractures.

Diagnostic Strategies. Radiologic evaluation of patellar fractures should include standard anteroposterior, lateral, and sunrise views. Most patellar fractures are obvious on plain radiographs, but vertical marginal fractures may be difficult to identify; they are obscured by the femur on the anteroposterior view and not seen at all on the lateral view. Close examination of sunrise (or equivalent) views may reveal an osteochondral avulsion fragment or marginal fracture (Fig. 54-11). Bipartite and multipartite patellae are common normal variants and should not be confused with fractures. Ossification centers are found at the upper outer quadrant of the patella and have smooth cortical margins. Comparison radiographs may be helpful because these anatomic anomalies are often bilateral. In some cases, MRI or arthroscopy may be needed to identify occult marginal fractures or free osteochondral fragments.

Management. If the patient can actively extend the knee without displacing the fracture, the retinaculum is intact, and the fracture may be treated nonoperatively. Nondisplaced patellar fractures usually are treated with a long leg cast for 4 to 6 weeks, with uniformly good results. Casting the knee in full extension relieves the patella of almost all stress during the healing period. For initial management, a knee immobilizer may be used. Patients should be instructed to use crutches, with partial weightbearing as tolerated, and should be referred for orthopedic or primary care follow-up.

For widened displaced transverse fractures, open reduction and internal fixation are necessary for optimal results. Although operative techniques vary among surgeons, tension band wire and suturing of the retinaculum often are used. A knee immobilizer or long leg posterior splint can be used initially to immobilize the extremity before definitive care is provided. Treatment options for displaced comminuted fractures include open reduction and internal fixation and partial or complete patellectomy.

Fracture fragment separation and dehiscence of the fracture repair are uncommon. They generally result from inadequate internal fixation or, in some cases, an inadequate period of immobilization. Avascular necrosis is rare. Range of motion generally is good after all procedures. Persistent patellofemoral pain and osteoarthritic symptoms are reported as late sequelae of patellar fractures in 56% of patients.

Patellar Dislocation

Anatomy and Pathophysiology. Traumatic patellar dislocation is a relatively common knee injury and can lead to recurrent patellar subluxation and dislocation. It is more common in children than in adults. Most cases are lateral extra-articular dislocations, and the mechanism of injury usually is a direct blow to the anterior or medial surface of the patella. It may occur from an athletic injury caused by a valgus stress combined with flexion and external rotation. In nearly all cases, disruption or sprain in the medial patellar retinaculum results from stretching of this structure as the patella subluxates laterally; subluxation usually indicates a stretched medial retinaculum, and dislocation suggests a tear. Although extra-articular patella dislocations are common, intra-articular dislocations are rare occurrences that must be considered in any patient with a locked knee.

The quadriceps angle (Q angle) is measured with the quadriceps contracted. The angle is formed by lines drawn on an anteroposterior radiograph from the tibial tubercle to the center of the patella and from the center of the patella to the anterior superior iliac spine. Normally this angle is 10 degrees or less in men; it may be 15 degrees in women. A Q angle exceeding these dimensions may predispose the patient to patellofemoral problems.

Clinical Features. Patients with lateral patellar dislocation may complain of the knee giving out accompanied by pain and swelling. Inability to bear weight and inability to flex the knee are common complaints. There may be a history of previous dislocation. Examination reveals a defect anteriorly with the patella deviated laterally. Tenderness along the medial joint line usually can be elicited by palpation, and an effusion may be present. Acute hemarthrosis is seen most commonly if there is an associated osteochondral fracture. Osteochondral fragments typically occur on the articular surface of the patella and may involve only cartilage (chondral fractures) or include a piece of underlying cortical bone. Patellar dislocations may reduce spontaneously, or the patient may self-reduce the dislocation, usually followed by formation of a large effusion.

The patellar apprehension test is used to aid the clinical identification of patients at risk for patellar dislocation or subluxation. The apprehension sign refers to the combination of manifestations of anxiety and anticipatory reactions observed in the patient when the examiner attempts to slide the non-displaced patella laterally. As a more objective element of this reactive pattern, the patient may forcefully contract the
quadriceps femoris muscle in an attempt to prevent such displacement and its associated pain. A positive result on the apprehension test indicates a tendency for patellar subluxation or dislocation. This test has no proven value and is not necessary in a patient with acute patellar dislocation, but it may be useful in establishing the diagnosis in patients who report an “event” that resolved spontaneously.

**Diagnostic Strategies.** Standard anteroposterior and lateral radiographic views generally are adequate for diagnosis. Obtaining a sunrise (skyline) view usually is not possible because of pain and inability to flex the knee. Radiographic findings include lateral deviation of the patella out of the trochlear groove, usually with an effusion. Radiographs should be examined for evidence of avulsion fractures.

**Management.** After dislocation is diagnosed, closed reduction should be attempted. Force or pressure should be directed anteromedially on the lateral patellar margin while gentle extension of the leg is attempted simultaneously. Uncommonly, patellar reduction may be difficult. Closed reduction can be achieved by applying downward pressure to the lateral aspect of the patella, creating an external rotational force that unlocks the medial patellar facet.

Postreduction radiographs are recommended and should reveal the patella in the trochlear groove. Osteochondral avulsion fragments may be visualized radiographically, and postreduction radiographs should be examined carefully for their presence. Radiologically evident intra-articular loose bodies may require arthroscopic removal.

Typically, traumatic patellar dislocations occur with disruption of the medial retinaculum but an intact lateral retinaculum, preventing internal rotation. Dislocations that are irreducible by conventional methods may be associated with significant internal rotation and lateral retinaculum pathology.

After successful reduction, the knee should be immobilized in full extension for 3 to 6 weeks, to allow adequate time for the medial retinaculum to heal. Ice, elevation, nonweight bearing, and analgesia provide additional benefit in the acute setting. The patient can be discharged with referral for orthopedic or primary care follow-up within 2 weeks. Although the incidence of recurrence may be decreased with appropriate therapy and proper patient selection, up to 44% will experience a recurrent dislocation, and more than one half of all patients with a primary patellar dislocation will continue to have symptoms of instability or anterior knee pain.

Patellar dislocations often recur and sometimes require surgery, involving arthroscopic release of the lateral retinaculum.

**Soft Tissue Injuries**

The knee is the most commonly injured joint. The ligaments of the knee function in conjunction with the joint capsule to limit varus-valgus (medial-lateral) bending of the knee and both anterior-posterior and varus-valgus translations of the knee. Ligament injuries to the knee may involve any or all of the ligaments and may range in severity from mild sprain to complete tears. Collateral ligament injury usually causes tenderness and pain along the joint line. Cruciate injuries pose more of a diagnostic dilemma because they are intra-articular structures.

**Cruciate Ligament Injuries**

The cruciate ligaments are the primary stabilizers for anterior and posterior displacement of the tibia on the femur. They are so named (Latin *crus* means “cross”) because they cross each other between their attachments. The ACL extends obliquely upward, medially, and backward from the anterior intercondylar area of the tibia to the medial aspect of the lateral femoral condyle. The ACL prevents excessive anterior displacement of the tibia on the femur and helps control rotation and hyperextension of the knee during cutting, twisting, and turning activities. It is the most commonly injured major ligament of the knee, with more than 100,000 new ACL tears occurring in the United States annually. The PCL passes upward, laterally, and forward medial to the ACL from the posterior intercondylar area of the tibia to the lateral aspect of the medial condyle of the femur. The PCL prevents excessive posterior displacement of the tibia on the femur, especially during flexion. The PCL is extremely strong, and injuries are relatively uncommon. Cruciate ligament injury is uncommon in children with open physes.

The ACL is commonly injured in sports. Numerous mechanisms of injury produce ACL disruption. Although ACL injuries can be caused by contact, they are more common in noncontact sports, with the plant-and-pivot and stop-and-jump mechanisms predominating. A direct blow to the flexed knee, as may occur in motor vehicle crashes (from the dashboard), and turf injuries with the knee flexed and the ankle plantarflexed also can result in an ACL injury.

One half of ACL injuries are associated with meniscal tears. The lateral meniscus is torn more commonly than the medial meniscus in acute ACL injuries, but in chronic ACL tears, the medial meniscus is more commonly involved. The classic “unhappy triad” of ACL, MCL, and medial meniscus injury may actually be less common than the association of torn ACL, torn MCL, and torn lateral meniscus.

The diagnosis of ACL injury often can be made from the history alone. Pain is the most common complaint with ACL rupture and usually is immediate. An audible “pop” at the time of injury is an important clue and is reported by approximately 70% of patients with ACL rupture. Patients also may report buckling, locking, or collapse of the knee and its inability to bear weight. The anterior drawer test is used to diagnose ACL injuries (see above).

PCL injuries are comparatively rare. Mechanisms include a fall onto the ground with the foot plantar-flexed (striking the tibial tubercle), a direct posterior blow to a flexed knee (e.g., a dashboard injury), hyperflexion, hyperextension, severe varus or valgus loading after failure of the collaterals, and knee dislocations. Nearly all PCL injuries are associated with other ligament injuries, including concurrent injuries of the MCL, ACL, or posterolateral complex.

PCL injuries are classified as partial (grade I or II) or complete (grade III) tears. Pain and swelling are common complaints with isolated PCL tears and with PCL tears having combined capsuloligamentous disruption. Popping or tearing sensations are infrequently noted, and instability usually is not immediately appreciated. Later, the patient may complain of feeling the femur “fall off” the tibia. The posterior drawer test (see above) is commonly done to assess for the integrity of the PCL.

Clinical evaluation is moderately sensitive for ACL tears and other intra-articular injuries with sensitivity for ACL injury ranging from 62 to 100% and 64 to 82% for meniscus injury. The lesions most difficult to diagnose are chondral fractures, tears in the ACL, loose bodies, and fibrotic fat pads.

**Collateral Ligament Injuries**

The medial stabilizers of the knee are the joint capsule and the MCL. The semimembranosus and pes anserinus are medial dynamic stabilizers. These structures resist valgus laxity and medial rotary instability. The MCL is a two-part structure with both a long superficial and a deep capsular component; the latter attaches to the medial meniscus and acts as a stabilizer for this structure. The MCL usually is injured
by a direct blow or impact to the lateral aspect of the knee, which imposes a valgus stress. Overall, MCL injury is the most common isolated knee ligament injury, and it is the injury most commonly associated with ACL injury. MCL injury usually does not require surgical treatment.

The lateral stabilizers of the knee are the LCL and the lateral joint capsule. Secondary contributors to lateral stability are supplied by the IT band, biceps tendon, and popliteal arcuate complex in the posterolateral corner of the knee. Resistance to varus stress is provided mainly by the LCL. Fibers descend from the lateral femoral condyle and insert at the fibula head. The lateral ligaments are under tension during standing and walking, when they are at or near maximal extension. The LCL usually is injured by a mechanism of hyperextension with varus stress, commonly accompanied by a direct blow or rotation. Injuries to the LCL are less common but more disabling than injuries of the medial aspect. The lower incidence of injury is attributed to the greater mobility of the LCL and overall greater stability of the lateral compartment. Varus injury is uncommon because the inner aspect of the knee is protected by the opposite leg. The forces necessary to produce LCL injury usually are greater than the forces required for medial injury, which partially explains the high frequency of associated injuries accompanying LCL injury. The tendon of the biceps femoris muscle attaches to the head of the fibula, just inferior to which the peroneal nerve passes. Because of this relationship, common peroneal nerve injury and biceps femoris tendon injury must be considered in patients with LCL injury.

The accuracy of the knee examination for ligamentous damage is enhanced if it is accomplished soon after injury and before the onset of swelling and pain, but the patient may not tolerate the examination in any case, and muscle spasm can obscure findings. In any case, ligamentous injuries are not emergencies and can be diagnosed definitively after the acute phase has passed. Focal tenderness at the origin or insertion sites suggests collateral ligament trauma but also can occur with muscular injury, osseous pathology, or meniscal tear. Range of motion should be documented and stability testing done to assess ligamentous injury as outlined previously.

**Diagnostic Strategies.** Plain radiography may be used before stress testing in cases of suspected ligamentous injury to rule out the possibility of an associated fracture. Although patients with isolated collateral ligament strain rarely show acute osseous pathology, the yield increases in cases with radiographic evidence of traumatic effusion and in cases in which cruciate ligament injury is suspected. The initial radiographic evaluation should include anteroposterior, lateral, intercondylar notch, and sunrise views. Each radiograph should be evaluated for possible osteochondral injuries, loose bodies, or avulsion injuries at the attachment sites of ligaments. The lateral capsular sign, associated with the Segond fracture (see Fig. 54-3) and fracture of the posterior aspect of the lateral tibial plateau, commonly are associated with ACL tear.

Arthroscopy is the “gold standard” modality for diagnosis of soft tissue injuries of the knee (ligaments or meniscus). MRI is useful but may miss small tears and anatomic abnormalities, and even if findings are normal, arthroscopy may still be necessary if symptoms persist. Moreover, abnormalities discovered at arthroscopy can be repaired. Therefore, many orthopedic surgeons recommend arthroscopy rather than imaging for diagnostic workup of knee pain when the causative disorder is not apparent on physical examination.

**Management.** Isolated collateral ligament injuries of all grades usually are managed nonoperatively, provided that the ACL is intact. The nonoperative approach should focus on controlling pain, restoring range of motion, regaining muscle strength, and protecting the knee from further injury. Appropriate initial therapy includes ice, NSAIDs, and immobilization if needed to control pain. Patients may be placed on a regimen of partial weightbearing or nonweightbearing using crutches. Orthopedic or primary care follow-up is advised, and a rehabilitative exercise program for quadriceps and hamstring strengthening may be instituted when the acute injury resolves.

Management of an ACL tear is controversial, because short-term disability and long-term arthritic sequelae are difficult to predict. Most young patients with a complete ACL tear who are active in sports require reconstructive surgery to stabilize the knee. Surgical repair usually is performed arthroscopically after a delay of 2 to 3 weeks to allow swelling to subside. Older patients and patients who do not participate in active sports may be managed conservatively with muscle strength training. If recurrent functional instability subsequently develops, reconstruction may be considered at a later date.

Isolated PCL injuries are unusual and typically are managed nonoperatively. These injuries often are painful but usually do not lead to instability. Rehabilitation involves quadriceps strengthening and functional bracing. Over 10 to 20 years, degenerative changes of the articular surface may result in stiffness and pain.

**Meniscal Injuries**

**Anatomy and Pathophysiology.** The medial and lateral menisci are crescent-shaped fibrocartilaginous cushions that sit on the superior articular surface of the tibia and provide a gliding surface for the femoral condyles. They function as shock absorbers and aid in the distribution of stress across the joint surface by providing a larger area of contact. They also act as secondary stabilizers by deepening the tibial plateau. Normal tibiofemoral articulation and function depend on meniscal integrity; damage or loss leads to osteoarthritis. The medial meniscus is firmly attached anteriorly and posteriorly to the joint capsule. The lateral meniscus is less firmly attached to the capsule and more mobile. The menisci move slightly forward with extension and backward with flexion. Because of its greater mobility, the lateral meniscus is less vulnerable to injury. The meniscus is avascular except at the peripheral third, which has the greatest potential to heal after injury.

Meniscal injury classically manifests with pain and tenderness at the joint line, effusion, and clicking or locking of the knee. Significant hemarthrosis is less likely and suggests cruciate ligament injury. Intermittent locking results from a meniscal fragment blocking joint movement. By contrast, persistently decreased range of motion results from prevention of knee movement by effusion and pain. Injury to the menisci may be from a single traumatic episode or a degenerative process, or a combination. The mechanism usually involves a twisting maneuver on a weight-bearing knee. The force required sometimes can be as slight as arising from a chair while turning.

Most meniscal tears are posterior.

**Clinical Features.** Meniscal injuries are unusual in children but become increasingly more common in adolescents and adults. An isolated meniscal tear should be suspected in a patient with a history of intermittent locking, effusion, giving way, and pain and physical examination findings of joint line tenderness and a positive result on McMurray’s test. Cruciate tears invariably result in immediate hemarthrosis; meniscal tears usually result in development of an effusion over 12 to 24 hours. A second, more common presentation is that of a patient with an unstable knee who has chronic ACL insufficiency and similar history and physical findings.

The cardinal sign of a meniscal tear is local pain and tenderness along the joint line. Joint line pain and tenderness are
especially apparent with extremes of flexion and extension. Not all tears of the menisci are symptomatic. Degenerative lesions of the posterior horn are relatively common in middle age and later and may be asymptomatic. The differential diagnosis for a torn meniscus is extensive and includes loose bodies, osteochondrotic lesions, tibial spine fractures, patellofemoral pain syndrome, popliteal tendinitis, plica syndromes, inflammatory arthritis, and discoid meniscus with or without a tear. Meniscal tears commonly accompany ACL tears.

**Diagnostic Strategies.** Diagnosis of acute meniscal injury is difficult, and more so in the presence of any acute knee injury, especially ACL tear. Meniscal injury cannot be diagnosed by plain radiography or CT scanning. Arthroscopy is the gold standard for diagnosis, and MRI is an alternative but may miss meniscal tears.

**Management.** Definitive treatment of a meniscal injury is not urgent. Unless the knee is locked and cannot be extended or flexed, a patient with a meniscal tear should be managed with analgesics, immobilization, ice, non-weightbearing, and referral for orthopedic or primary care follow-up. Surgery is reserved for cases with persistent symptoms that limit activity. Surgery involves arthroscopic exploration. The torn meniscal fragment is reattached if it is well vascularized; otherwise, it is resected.

**Overuse Syndromes**

Overuse syndromes result from repetitive trauma and inflammation. The typical complaint is knee pain, often localized to one of three particular areas: the medial aspect, the lateral aspect, or the peripatellar region. Medial knee pain may be caused by subluxation of the patella, a stress fracture of the upper third of the tibia, anserine bursitis or tendinitis, and MCL strain related to excessive foot pronation. Lateral knee pain may be caused by iliotibial or popliteal tendinitis, LCL strain, or stress fracture of the fibula. Anterior pain is typical of lateral patellar compression syndrome, peripatellar tendinitis, and patellofemoral syndrome, the most common cause of knee pain.

**Patellofemoral Pain Syndrome**

**Anatomy and Pathophysiology.** The *patellofemoral* pain syndrome refers to the clinical presentation of anterior knee pain related to changes in the patellofemoral articulation. *Chondromalacia patellae* describes softening of the articular cartilage. Correlating pathologic changes on the surface of the patella and clinical symptoms has been difficult, and the pain mechanism has not been precisely defined.

**Clinical Features.** As noted, the patellofemoral pain syndrome is the most common cause of knee pain. Affected patients generally are 10 to 20 years of age and often have difficulty describing their symptoms clearly. The pain usually begins gradually and commonly is not related to trauma. One knee usually is more affected than the other. The knee is more painful with prolonged flexion (e.g., from sitting in a movie theater), and the discomfort typically is accentuated by stair climbing and kneeling. The patient may have instability related to patellar subluxation or dislocation. The syndrome occurs both in athletes and in elderly patients who have arthritis affecting the patellofemoral joint. Considerations in the differential diagnosis include tears of the menisci, plica syndrome, inflammatory or degenerative arthritis, ligament injuries, and overuse syndromes (e.g., prepatellar bursitis, patella tendinitis).

The physical examination should begin with observation. The patient may ambulate with an antalgic gait. A tibiofemoral joint effusion may be present. The patellar facets may be tender. Classically, compression of the patella against the femur, with the knee extended, causes pain. There may also be apprehension to medial or lateral subluxation.

**Diagnostic Strategies.** Plain films are typically normal, and other more advanced studies should be undertaken only if other diagnoses are being considered.

**Management.** Most patients, regardless of the cause of their condition, respond to a rehabilitation program. Conservative treatment for patellofemoral pain usually is effective, with most patients responding to one or more of four types of treatment: (1) exercises to strengthen the quadriceps, (2) brace support of the patellofemoral mechanism, (3) activity modification limiting flexion, and (4) medications such as NSAIDs for pain. The initial goal is to reduce pain and improve function, with emphasis placed on strengthening the vastus medialis oblique muscle. The patient should receive appropriate referral to ensure that an optimal rehabilitative scheme is designed.

**Iliotibial Band Syndrome**

The IT band is a strip of fascia lata that extends from the iliac crest to the lateral tibial tubercle. It connects the lateral femoral condyle and the lateral tibia and stabilizes the knee joint in extension. Irritation due to overuse can cause inflammation of a bursa underlying the IT band at the lateral femoral epicondyle, resulting in lateral knee pain. The syndrome is most common in distance runners and is more likely in hyperpronators. Physical findings include localized tenderness of the lateral femoral epicondyle and IT tightness or pain, elicited by Ober’s or a related test. In Ober’s test, the patient lies on the side with the unaffected leg down, flexed to 90 degrees at the hip and knee. The affected hip is abducted, the knee extended, and then the hip is allowed to return to neutral adduction with gravity. Failure of the hip to adduct fully with gravity or reproduction of pain at the lateral knee indicates IT tightness or inflammation, respectively. Radiographs are normal in appearance.

Considerations in the differential diagnosis include early degenerative joint disease, cystic or torn lateral meniscus, lateral capsular strain, lateral tibial or femoral condyle osteonecrosis, stress reactions, chondromalacia, and popliteus tendinitis. Treatment involves rest, ice, and NSAIDs during the acute phase, followed by an IT band stretching regimen, improved footwear and orthotics when indicated, and gradual return to previous levels of activity. Steroid injections are helpful for refractory cases, and surgical release is uncommonly required.

**Peripatellar Tendinitis**

Peripatellar tendinitis, or jumper’s knee, refers to a spectrum of patellar tendon and extensor mechanism abnormalities that result from chronic repetitive stress from jumping, running, or cutting. Microscopic tears occur in the tendon. Treatment involves NSAIDs, rest, and activity modification. Local steroid injections are not recommended. For highly competitive athletes and patients in whom conservative treatment fails to effect improvement, surgery with débridement of abnormal tissue may be performed.

**Plica Syndrome**

Plicae, or redundant folds of synovium, are normal embryologic structures that persist in the adult knee. Repetitive bouts of synovitis within the plica may result in a tight inelastic band that interferes with knee motion. Patients typically complain
of pain over the region of the medial femoral condyle brought on by activity but also occurring after sitting for prolonged periods. A snapping sensation is another commonly reported symptom as the plica sweeps across the femoral condyle. Other nonspecific symptoms include intermittent swelling, locking, weakness, and stiffness. The physical examination often elicits tenderness over the medial femoral condyle but not the medial joint line; the latter finding would be more typical of a medial meniscal lesion. An effusion, crepitus, loss of motion, quadriceps atrophy, and a positive result on McMurray’s test may be noted as well.68

Plain radiography is necessary to exclude other causes of knee pain but is of no value in diagnosing plica syndrome, for which arthroscopy usually is required. Most plicae are incidental arthroscopic findings unrelated to underlying knee pathology. Medial patella is more likely to be related to patellofemoral maltracking than to plica syndrome. Likewise, anteromedial joint line tenderness is more likely to be related to a meniscal tear than to a pathologic plica.

Treatment involves rest and NSAIDs. When the acute symptoms have resolved, a rehabilitation program is instituted to emphasize quadriceps strengthening and stretching. Arthroscopic excision of pathologic plica may be necessary if conservative treatment fails.

Popliteus Tendinitis

The popliteus is a small, flat muscle that originates on the lateral femoral condyle and inserts on posteromedial tibia, capsule, and lateral meniscus. It passes beneath the lateral head of the gastrocnemius. Its tendon is surrounded by a bursa that separates it from the fibular collateral ligament, femoral condyle, and capsule. Functionally, it prevents external rotation of the tibia and withdraws the lateral meniscus during flexion to prevent impingement between the femur and the tibia. A third function, along with the quadriceps and PCL, is to stabilize the knee by preventing forward displacement of the femur on the tibia. Popliteal tendinitis usually occurs in athletes and often causes localized pain over the posterior or posterolateral aspect of the knee. Running and walking downhill exacerbate symptoms. Usually there is no history of effusion, locking, or giving way.69

On physical examination, tenderness is noted at the insertion point of the muscle, medial to the insertion of the lateral head of the gastrocnemius. Because of its close relationship to other soft tissue structures, the diagnosis may be difficult. The Webb test is performed with the patient supine and the knee flexed to 90 degrees. The leg is rotated internally, and the patient is asked to resist the examiner’s attempt to externally rotate the leg. Reproduction of symptoms suggests the diagnosis. Considerations in the differential diagnosis for popliteus tendinitis include injury of the biceps femoris insertion, lateral meniscus, lateral gastrocnemius, and IT.

Treatment involves rest, ice, NSAIDS, and quadriceps strengthening and stretching. Most athletes can gradually return to activity in 10 to 14 days.

Bursitis

The knee has several bursae, which decrease friction between moving structures. They usually are thin but with repeated stress may become thickened and fluid-filled. The prepatellar bursa is located between the patella and the skin. The superficial infrapatellar bursa is located between the tibial tubercle and the skin. The deep infrapatellar bursa is located between the posterior margin of the distal part of the patellar tendon and the anterior aspect of the tibia. The suprapatellar bursa is not a true bursa but rather is an extension of the tibiofemoral joint capsule. The anserine bursa separates the pes anserinus from the distal portion of the MCL and the medial tibial condyle. As noted previously, pes anserinus means “goose foot,” and anserine means “related to the pes anserinus.” The term derives from the fact that the bursa underlies the anserine tendon, a three-forked structure constituting the insertion of the gracilis, sartorius, and semitendinosus muscles.

Bursitis is caused by repeated stress, infection, local trauma, crystal deposition, or systemic inflammatory arthropathy. Bur- sitis must be differentiated from knee effusion. Prepatellar bursitis is characterized by swelling with effusion of the superficial bursa overlying the lower pole of the patella. Passive motion usually is fully preserved, and the pain generally is mild. The disorder usually is caused by pressure from repetitive kneeling on a firm surface (“housemaid’s knee”). The prepatellar bursa also is a common site of septic bursitis, and a common error is to confuse this entity with a septic knee (involving the tibiofemoral joint).

Anserine bursitis involves pain and tenderness at the proximal medial tibia, a few centimeters inferior to the medial joint line. It occurs most commonly in obese women in association with osteoarthritis of the knee but also may occur from overuse, especially in runners. It is characterized by a relatively abrupt onset of knee pain with localized tenderness and puffiness at the pes anserinus. It can be confused with a medial meniscal or MCL tear.

Radiographic studies may reveal soft tissue swelling. Ultra-sound imaging also may detect the fluid collection. MRI may be helpful but is not required on an urgent basis. With any uncertainty regarding the possibility of infection, the bursa fluid should be aspirated, and Gram staining, culture, cell count, and crystal analysis of the aspirate should be performed.

Septic (bacterial) bursitis requires antibiotic treatment, with operative drainage in refractory cases. Aseptic (inflammatory) bursitis is treated with ice, rest, anti-inflammatory drugs, and injection of bupivacaine and corticosteroids—the last, of course, being contraindicated in the presence of infection. All of the bursae of the knee may be injected with steroids; in the ED, steroid injection of the anserine and prepatellar bursae is most common.

Osteoarthritis

Osteoarthritis is joint inflammation due to degeneration. The incidence increases with age, obesity, trauma, and meniscoc- tomy. Pain usually is the initial complaint and typically is aggravated by activity and relieved by rest. Locking, giving way, and a sensation of instability may be associated complaints. The physical examination may reveal a gross angular deformity—either genu valgum (knock-knee) or genu varum (bow-leg)—and an antalgic gait may be noted. The joint line of the involved compartment usually is tender. Osteoarthritis may involve one or all compartments of the knee.

Standard anteroposterior weight-bearing radiographs may reveal narrowing of the joint spaces, peripheral osteophyte formation, subchondral sclerosis, and cyst formation; they also may show angular deformity of the knee. Lateral and oblique views may show the presence of peripheral osteophytes and loose bodies. Tangential sunrise views are needed to evaluate the patellofemoral joint for osteophytes, sclerosis, and maltracking.

Treatment consists of activity modification, NSAIDs, bracing, and strengthening exercises. A cane may be helpful
to unload the affected extremity and provide symptomatic relief. If the patient is obese, weight reduction is recommended. Surgical treatment is reserved for severe cases and may involve osteotomy, hemiarthroplasty, or total knee arthroplasty.

**Septic Arthritis**

The knee is the most common joint affected with septic arthritis. Hematogenous seeding is the most common route of spread, but joint trauma also is a frequent cause. Bacterial spread usually affects the vascular synovial membrane and then extends into the joint. *Staphylococcus aureus* is the most common pathogen, but *Neisseria gonorrhoeae* also must be considered, because the typical treatment is vancomycin for the former and ceftriaxone for the latter. Moreover, the latter is a reportable disease requiring contact tracing. To prevent septic arthritis in the ED setting, all open joint injuries should be treated by operative washout and antibiotics, and clinicians should avoid performing arthrocentesis through infected skin, which can seed the joint.

**Baker’s Cyst**

Baker’s cyst (popliteal cyst) is a herniation of the synovial membrane through the posterior aspect of the capsule of the knee (Fig. 54-12). It results from an enlarging knee effusion of any cause. A mass is palpable in the posteromedial corner of the knee and often produces pressure, pain, and limitation of range of motion. Rupture of the bursa with resultant escape of fluid into the calf may produce a clinical picture similar to that of deep vein thrombosis or compartment syndrome. In this circumstance, ruptured Baker’s cyst is a diagnosis of exclusion (i.e., thrombosis should be ruled out). Treatment is directed at the underlying intra-articular pathology.

---

**Figure 54-12.** Baker’s cyst is an extension of the semimembranosus bursa posteriorly. This bursa often is connected with a joint cavity.
MECHANISMS OF INJURY AND MANAGEMENT

Proximal Extra-articular Tibial Fractures

Subcondylar Tibial Fractures

Subcondylar tibial fractures usually are associated with tibial plateau fractures, especially bicondylar fractures. Subcondylar fractures involve the proximal tibial metaphysis and typically are transverse or oblique. The mechanism of injury involves a rotational or angular stress accompanied by vertical compression. Examination reveals tenderness and swelling of the involved area. A hemarthrosis may indicate extension of the fracture into the joint or associated ligamentous injury. Routine radiographic views usually are adequate in showing the fracture line. ED management includes ice and immobilization with a long leg posterior splint. Stable extra-articular nondisplaced transverse fractures usually are treated conservatively with a long leg splint, followed by delayed casting on the outpatient basis. In children, casting (with adequate padding) is sometimes performed acutely. Comminuted fractures or fractures associated with an intra-articular component require open reduction and internal fixation and may be treated in the acute setting.

Tibial Tubercle Fractures

Anatomy and Pathophysiology. The tibial tubercle is located at the proximal anterior border of the tibial shaft and is the insertion point of the patellar ligament. The proximal tibial epiphysis and the tibial tuberosity develop from two separate ossification centers that coalesce during adolescence. Epiphyseal ossification terminates in late adolescence.

Avulsion fractures of the tibial tubercle are uncommon. They occur predominantly in adolescent boys. The injury typically occurs near the end of growth, when endochondral ossification of the physeal cartilage of the tibial tubercle occurs. Avulsion fractures mainly occur as an indirect injury during activity. The mechanism of injury has been described as a violent flexion of the knee against a tightly contracted quadriceps muscle, which also can cause patellar tendon rupture. The Watson-Jones classification describes three grades of injury depending on the extent of displacement (Fig. 54-13). In type I injuries, the tubercle is hinged upward without displacement from the proximal base. The type II injury has a small portion of the tubercle avulsed, but it is retracted proximally; the articular surface is not involved. Type III fractures are more severe and extend across the articular surface; displacement of the fragment and often comminution are features.

Clinical Features. Physical examination reveals acute tenderness and swelling at the anterior aspect of the knee and proximal tibia. Depending on the type of injury, functional disability may range in severity from extensor lag to complete loss of active extension. Hemarthrosis is evident with type III injury because of intra-articular fracture extension across the proximal epiphysis.

Diagnostic Strategies. Plain radiographs usually are adequate for diagnosis. The lateral view shows the avulsion fracture, number of fragments, and amount of displacement. Swelling of the overlying soft tissue is evident. Comparison views may be necessary when a type I injury is suspected.

Management. Treatment depends on the degree of displacement and the presence of joint involvement. Nondisplaced type I avulsions are treated with cast immobilization with the knee in extension until healing results. Minimally displaced type II avulsions may be treated similarly if the displacement can be reduced by external manual maneuvers. Displaced type III fractures are treated by open reduction and internal fixation to restore proper biomechanics and joint congruity. Fixation screw and tension band wiring techniques have yielded excellent results. After a period of immobilization and progressive rehabilitation, most patients are able to return to full activity.

Complications of tibial tubercle fractures are rare and include genu recurvatum (backward curvature of the knee), patella alta, meniscal tears, failure of surgical fixation, and subsequent heterotopic ossification and osteonecrosis of the tubercle. If the involved growth plates are closing at the time of injury, premature physeal closure can rarely result in a significant recurvatum deformity.

Osgood-Schlatter Disease

Anatomy and Pathophysiology. Adolescents are susceptible to the development of Osgood-Schlatter disease, also known as osteochondritis of the tibial tuberosity or apophysitis of the tibial tuberosity. This common condition results from traction of the distal patellar tendon on the tibial tubercle, causing repetitive microtrauma with subsequent healing of the physis.
of the tibial tuberosity. This traction apophysis occurs during the adolescent growth spurt, usually in athletically active children.

**Clinical Features.** The disease is characterized by painful swelling over the tibial tubercle, which is exacerbated by activity, is relieved by rest, and is usually of several months’ duration. The tubercle may appear abnormally prominent, often on both sides. Pain is elicited on resisted extension of the flexed knee, and occasionally an extensor lag may be noted. Tenderness is most pronounced at the insertion of the patellar tendon. Bilateral involvement is noted in 20 to 30% of patients.†

**Diagnostic Strategies.** The diagnosis of Osgood-Schlatter disease is based on clinical signs and symptoms. Plain radiography of the knee may be useful to exclude other pathologic entities (e.g., tumors, infection, avulsion fractures) but generally is not required. Radiographs are normal in appearance or reveal preexisting bone abnormalities (e.g., tumors, infection, avulsion fractures) but generally is not required. Radiographs are normal in appearance or reveal preexisting bone abnormalities. Management. Treatment varies according to the acuteness of the symptoms and the skeletal age of the patient. Initially, rest, ice, and analgesics are the mainstays of therapy. As symptoms subside, a rehabilitation program that stretches and strengthens the quadriceps should be instituted. Knee orthoses are used to damp the pull of the extensor mechanism on the weakened tibial apophysis. Immobilization is reserved for the unreliable patient who will not or cannot comply with the program of relative rest in which aggravating activities are avoided. For children with severe symptoms, immobilization for 2 to 3 weeks may be used. Surgical repair may be required if the conservative treatment fails, but it cannot be implemented until the epiphysis is closed, at which time the problem usually is resolved.

### Tibial Shaft Fractures

**Anatomy and Pathophysiology.** The tibia and fibula are tightly bound to each other by the syndesmotic ligament. This strong band of tissue can transmit energy such that the tibia and fibula may be fractured at nonadjacent sites. The fibula remains intact in only 15 to 25% of tibial shaft fractures. Tibial shaft fractures are associated with a high incidence of infection, delayed union, nonunion, and malunion, in part because of the poor soft tissue coverage of the anterior tibia.

Transverse tibial diaphyseal fractures typically result from high-energy direct trauma. Low-energy rotatory and compressive forces often result in spiral or oblique fractures.

The **toddler’s fracture** is a nondisplaced spiral fracture of the distal tibia in a child 9 months to 3 years of age. The classic distal fracture often relates to accidental trauma, as opposed to a midshaft fracture, which suggests abuse.

Tibial fractures also may occur without trauma. Stress fractures occur most commonly in the tibial shaft. Pathologic fractures may be caused by metabolic bone disease, osteomalacia, or neoplasm.

In children, buckle fractures and greenstick fractures are common in the tibia and fibula. A **buckle fracture** is manifested radiographically as an often subtle buckling without angulation, in contrast with the smooth line formed by the normal cortex. A **greenstick fracture** is a bending fracture, with a break in the periosteum and cortex of the convex side of the angulated bone, while the concave side of the bone is spared. Both of these fractures are stable with an intact periosteum so that swelling, crepitance, and mobility at the fracture site are minimal.

**Clinical Features.** Tibial shaft fractures cause pain, swelling, and localized deformity, usually angulation or rotation of the foot. Determination of vascular integrity is the priority. Distal dorsalis pedis and posterior tibial pulses should be assessed; however, vascular injury is a rare complication of these fractures. Neurologic injury, by contrast, is common, particularly injury of the peroneal nerve. Motor function of the peroneal nerve is checked by testing active ankle and toe dorsiflexion (deep peroneal nerve) and active foot eversion (superficial peroneal nerve). Sensory function of the peroneal nerve is documented by testing sensation in the first dorsal web space in the foot (deep peroneal nerve distribution) and sensation of the dorsal lateral foot (superficial peroneal nerve distribution).

Integrity of the posterior tibial nerve is assessed by checking for the presence or absence of plantar sensation. Significant soft tissue damage also may accompany tibial shaft fractures. Compartment syndrome may be a complication of tibial fractures and usually develops within the first 24 to 48 hours.

**Diagnostic Strategies.** Anteroposterior and lateral radiographic studies document the fracture, define the fracture pattern, and identify any associated bone loss (Fig. 54-14). The knee and ankle should be included in both views, and radiographs of the pelvis and ipsilateral femur may be required to assess for associated injuries. Postreduction views should be taken after any manipulation of the extremity and should include the knee and ankle joints so that alignment of the proximal and distal joint surfaces can be determined.

**Management.** The initial management of closed tibial shaft fractures consists of immobilization in a long leg posterior splint applied with the knee in 10 to 20 degrees of flexion. The splinting procedure may require analgesia and sedation. Generally, after fractures are immobilized, pain decreases. If the patient complains of continued severe pain after immobilization, a complication such as compartment syndrome, nerve root compression, or limb ischemia should be considered. Circumferential casts generally are avoided in the acute setting because of the risk of compartment syndrome, although some orthopedists will cast pediatric fractures in the acute phase. Initial hospitalization is indicated for most patients with significant tibial shaft fractures to allow adequate pain control and observation for compartment syndrome.

**Figure 54-14.** Tibiofibular fracture. A, Anteroposterior view. Comminuted fractures of the tibial and fibular shafts are present. Note the obliteration of the normal soft tissue planes secondary to edema or hemorrhage. B, Lateral view. (From Rosen P, et al: Diagnostic Radiology in Emergency Medicine. St. Louis, Mosby, 1992, p 198.)
Open fractures should be covered by a sterile dressing. Antistaphylococcal antibiotics (typically cefazolin) should be given, with consideration of agents active against multidrug-resistant *Staphylococcus aureus* (MRSA). Gentamicin is added for severely contaminated wounds.\textsuperscript{74} Tetanus vaccination status should be updated as indicated. A long leg posterior splint should be applied. (This applies to all open fractures.) Emergency operative débridement with external or internal fixation is recommended as soon as possible for open tibial fractures with significant soft tissue disruption. Osteomyelitis is more likely with open fracture, significant soft tissue disruption, and longer time from contamination to definitive surgical management.

In general, tibial fractures are slow to heal. The average time to union is approximately 20 weeks for stable tibial shaft fractures caused by a low-energy mechanism and more than 30 weeks for unstable fractures caused by a high-energy mechanism.\textsuperscript{75} Delayed union describes fracture segments that have not united after 24 weeks or that show no radiographic evidence of callus formation for 3 consecutive months. Nonunion is a radiographic diagnosis, with a finding of rounded, well-corticated edges of the major fracture fragments. It is much more common in adult long bone fractures than in childhood fractures, which generally heal rapidly. Delayed vascular injuries of the shank vessels, including pseudoaneurysm, arteriovenous fistula, and deep vein thrombosis, also may occur as a complication of tibial shaft fractures. Fat embolism also may occur acutely, especially after reamed nailing. Additional late complications include malrotation of the leg, refracture, and reflex sympathetic dystrophy.

### Proximal Fibula Fractures

**Anatomy and Pathophysiology.** Isolated fibular fractures are relatively unimportant because the fibula is non-weight-bearing. The mechanism of injury usually is a direct blow to the lateral aspect of the leg or an indirect varus stress to the knee. An important exception is *Maisonneuve fracture* (Fig. 54-15). This injury involves a medial ankle disruption (deltoid ligament tear or medial malleolar fracture), with complete tearing of the syndesmotic ligament joining the tibia and fibula, and fracture of the proximal fibula. Consequently, the fibula floats free relative to the tibia, resulting in an unstable ankle mortise, for which surgical fixation is required. The possibility of this injury mandates examination of the proximal fibula in all medial ankle injuries.

**Clinical Features.** Isolated fibular shaft fractures cause lateral leg pain that is exacerbated by walking. Local pain, swelling, and tenderness at the fracture site may be elicited, although signs and symptoms can be subtle. A thorough evaluation should be done to exclude serious associated occult neurovascular or ligamentous injuries. The common peroneal nerve course around the neck of the fibula and may be contused or lacerated at the time of injury. The LCL of the knee may be torn or strained in association with the fracture, and anterior tibial artery injury with thrombosis may occur.

**Diagnostic Strategies.** Anteroposterior and lateral radiographic views should include the knee and ankle joints.

**Management.** Isolated fibular shaft fractures are treated symptomatically with ice, analgesia, and nonweightbearing. Immobilization in a long leg cast is rarely done but may provide symptomatic relief beginning 2 days after the acute injury. Weightbearing may be advanced progressively as tolerated; pain should be avoided. Patients with nondisplaced or minimally displaced fractures may have little pain and tolerate crutch walking without casting. In general, isolated fibula shaft fractures can be managed on an outpatient basis and heal without complication.

For severely displaced fibular shaft fractures or fractures with associated peroneal nerve deficit (i.e., footdrop), orthopedic consultation is indicated. Cast immobilization is not recommended in cases with concomitant nerve damage, and follow-up is scheduled at a shorter interval from injury. Elective surgical repair may be indicated if function does not return. Maisonneuve fracture results in an unstable ankle, and open reduction and internal fixation usually are required.

### Proximal Tibiofibular Joint Dislocations

**Anatomy and Pathophysiology.** The proximal tibiofibular joint is a small synovial joint between a circular or oval facet on the head of the fibula and a similar facet on the inferior aspect of the lateral tibial condyle. The proximal tibiofibular joint is stabilized by the joint capsule and the anterior and posterior tibiofibular ligaments. Dislocation of the proximal tibiofibular joint is rare, occurring most commonly in adolescents and young adults because of its association with motor vehicle crashes and sports injuries.\textsuperscript{76} Several types of dislocations of the joint have been described: anterolateral dislocation is the most common and usually is caused by a fall on a flexed, abducted leg. Posterior medial dislocation generally is caused by a direct blow to the flexed knee and is more often associated with peroneal nerve injury. Superior dislocation is associated with ankle diastasis and typically occurs simultaneously with an ankle fracture.

**Clinical Features.** The patient may complain that the knee feels “out of joint,” or if the problem is intermittent, the knee may lock or give way periodically. Physical examination reveals tenderness and swelling over the proximal fibula and tibiofibular joint. In the absence of associated injury, findings on knee
examination are otherwise normal, with full range of motion and no joint line tenderness or effusion.

**Diagnostic Strategies.** Plain radiography may confirm the diagnosis, although CT may be required. On the anteroposterior view, the fibular head is displaced laterally, and the interosseous space is widened. Comparison views of the uninjured knee may be necessary to appreciate these findings.

**Management.** Traumatic proximal tibiofibular dislocation is treated initially with closed reduction. If the patient seeks treatment within a few days of injury, reduction of an anterolateral dislocation can be accomplished in the ED by flexing the knee to 90 degrees, evertting the ankle, and applying direct pressure to the head of the fibula.76 Orthopedic referral and immobilization of the knee for a minimum of 3 to 6 weeks are necessary after reduction. If closed reduction fails, the patient may require open reduction, with repair of the torn capsule ligaments and pinning. For recurrent dislocations or injuries that do not respond to initial treatment, resection of the proximal fibula or arthrodesis may be effective.

### Stress Fractures

**Anatomy and Pathophysiology.** The tibia is a common site of stress fracture. Usually the stress fracture occurs on the tibial shaft. Fractures typically are horizontal or oblique and uncommonly longitudinal.77 Other sites of stress fracture include the femur, fibula, tarsals (especially navicular), and metatarsals. Stress fractures result from overuse. Stress fractures, which occur as a result of excessive repetitive force to normal bone, are distinguished from pathologic fractures, which occur as a result of normal forces acting on abnormal bone (due to osteoporosis or tumor, for example).

**Clinical Features.** Bone pain and tenderness without a history of direct trauma are characteristic. The most important historical information includes a recent increase in physical activity, training on hard surfaces, and inadequate footwear. The pain usually is insidious in onset and progressive but may be sudden. Pain is usually relieved with rest. The differential diagnosis for lower leg pain also includes shin splints, exercise-induced compartment syndrome, contusion, muscle strains, tendinitis, periostitis, and interosseous membrane strains. The physical examination may reveal localized bone tenderness and swelling of the overlying soft tissues. Usually there is no muscle atrophy, weakness, or restriction of joint range of motion.

**Diagnostic Strategies.** The radiographic findings vary depending on the location of the fracture and stage of healing. Approximately one third of stress fractures are evident radiographically at the time of initial diagnosis, compared with one half after 2 to 6 weeks. The radiographic findings often are subtle and may include periosteal new bone, sclerosis, and a lucent line perpendicular to the cortex. MRI can diagnose the condition earlier and more accurately than plain films.77

If a stress fracture of the lower extremity is suspected and findings on initial plain radiography are unremarkable, follow-up evaluation at 10 days to 2 weeks may detect radiographic signs of fracture after a period of inactivity. Evidence of healing (periosteal reaction) in response to treatment usually is sufficient to confirm the diagnosis.

**Management.** Most tibial and fibular stress fractures can be treated nonoperatively. Activity should be decreased for 3 to 6 weeks to allow for healing, and serial radiographs should be obtained. In those rare instances in which walking causes pain, a cast and nonweightbearing may be required. Serial radiographs are used to evaluate healing. Rare cases of nonunion require surgery.

### Compartment Syndrome

Compartment syndrome is due to increased pressure within a fascial compartment, leading to necrosis of muscle and nerve and is discussed in Chapter 46.

### Soft Tissue Injuries Involving the Lower Leg

#### Strains

**Gastrocnemius Strain**

The medial head of the gastrocnemius muscle often is strained in athletics and sometimes ruptures. On physical examination, a palpable gap may be identified in the substance of the muscle, and point tenderness may be elicited in the medial and inferior borders of the muscle belly. Any attempted active or passive ankle dorsiflexion elicits pain.

Gastrocnemius strain or rupture may be confused with rupture of the plantaris tendon, which causes tenderness, swelling, and ecchymosis in the proximal calf; rupture of a Baker’s cyst, which may result in the escape of fluid into the calf; thrombophlebitis; and Achilles tendon rupture, which typically results in a palpable gap just proximal to the calcaneous. The diagnosis is made clinically, although a soft tissue defect may be seen on plain radiographs of large ruptures. MRI can confirm the diagnosis but is rarely necessary.

A mild partial rupture of the medial head of the gastrocnemius can be treated with rest and nonweightbearing for several days. Treatment for more extensive incomplete ruptures involves casting for 8 weeks with the ankle plantarflexed. For a complete tear, most orthopedists recommend surgical repair to restore normal length and tensile strength. Acute compartment syndrome can complicate gastrocnemius strain.

**Plantaris Strain and Rupture**

The plantaris is a small, variable muscle that originates at the lateral condyle of the femur and passes beneath the soleus to insert on the Achilles tendon. It is a feeble flexor of the knee and planatar flexor of the ankle joint with little functional significance. Rupture may occur at the myotendinous junction with or without an associated partial tear of the medial head of the gastrocnemius muscle. A strain of the more proximal plantaris muscle also may occur as an isolated injury or in conjunction with injury to the ACL of the knee. The patient may describe a sudden sharp snap in the posterior calf followed by a duller deep ache, which may be disabling. Tenderness is greatest just lateral to the midline of the posterior calf. Treatment is symptomatic.

**Shin Splints**

Shin splints refers to anterior tibial pain occurring during or after exercise. The most common causes are a tibial stress reaction or periostitis. Tibial stress reactions are microfractures caused by stress placed on the tibia and are distinct from gross stress fractures, which predispose the affected bone to complete fracture.

The physical examination reveals localized tenderness over the tibia, usually at the junction of the middle and lower thirds. Radiographic studies are not helpful in the diagnosis of shin splints and also cannot exclude a tibial stress fracture with certainty. Treatment is symptomatic: rest, NSAIDs, ice, and
supportive footwear. The patient should be referred for outpatient evaluation, where conservative therapy can be continued or further diagnostic workup can be pursued.

Foreign Bodies

Foreign bodies such as plant matter (e.g., thorns) are commonly encountered in the leg. Missed retained foreign bodies to the lower leg can be the cause of cellulitis, abscess, necrotizing fasciitis, and gangrene. Plain films are a necessary part of evaluation but will be unhelpful when the foreign body is radiolucent. Ultrasound imaging is superior for diagnosis and localization, and fluoroscopy and MRI are alternatives. Surgical exploration is sometimes necessary. Extraction is difficult, and deep foreign bodies should be removed by a surgeon, often in the operating room.

Acknowledgments

We are grateful for the previous contributions of Dr. Robert Antosia and for the assistance of Dr. James Andruchow with preparation of this chapter for the present edition.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
To him whose feet hurt, everything hurts.

Socrates

The ankle and foot are highly evolved structures designed to support the body's weight and to facilitate locomotion over varied terrain. Findings related to ankle and foot injuries often are subtle, and diagnosis may be delayed or missed, particularly in cases of multiple trauma.

The ankle and foot are best approached clinically as a single functional unit. Although they are discussed sequentially in this chapter, their mechanisms of injury overlap, and a pathologic condition in one location may accompany an associated pathologic condition in another.

ANKLE

■ PRINCIPLES OF DISEASE

Anatomy

The ankle joint is the articulation of the tibia and fibula with the talus. The dome of the talus fits securely into the "mortise" formed by the medial malleolus, the horizontal articular surface of the tibia (the plafond), and the lateral malleolus. The stability of the ankle depends on the bony and ligamentous integrity of the mortise. The calcaneus also is important to the motion and stability of the ankle.

The ankle comprises three primary articulations: the inner surface of the medial malleolus with the medial surface of the talus; the distal tibial plafond with the talar dome; and the medial surface of the lateral malleolus with the lateral process of the talus. These three articular surfaces are contiguous, lined with cartilage, and enclosed by a single joint capsule. The distal tibia also articulates with the distal fibula just proximal to the talus, forming the distal tibiotalar joint. Collectively, these articulations are called the talocrural joints.

Three sets of ligaments—the syndesmotic ligaments, the lateral collateral ligaments, and the medial collateral ligaments—support the ankle joint and are essential to its stability (Figs. 55-1 and 55-2).

Tendons course through the ankle in four geographic groups. The flexor retinaculum tethers the tendons of the tibialis posterior, the flexor digitorum longus, and the flexor hallucis muscles behind the medial malleolus. The peroneal retinaculum and tendon sheath tether the peroneus longus and brevis tendons behind the lateral malleolus. The extensor retinaculum tethers the tendons of the tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius over the anterior aspect of the ankle. Posteriorly, in the midline, lie the Achilles and plantaris tendons.

Pathophysiology

Ankle movements are complex, often involving more than one joint. It is best to consider the group of joints about the ankle as one unit, the ankle joint complex. This complex, which is made up of the talocrural joints and the talocalcaneal joints, or the subtalar joints, allows movements along several axes of motion.1 Dorsiflexion (extension) and plantar flexion (flexion) of the ankle joint complex occur primarily at the talocrural joints, rotating about the horizontal axis that passes through the medial and lateral malleoli (Fig. 55-3; see also Fig. 55-5). Motions of the ankle joint complex in conjunction with the midtarsal joints include inversion and eversion, which are rotational movements about the oblique subtalar axis involving the subtalar joint (see Fig. 55-3A), and abduction (external rotation) and adduction (internal rotation), which are rotational movements about the longitudinal axis of the tibia (see Fig. 55-3B).

The components providing stability to the ankle are best conceptualized as a ringlike structure surrounding the talus2 (Fig. 55-4). Disruption of one element of this ring does not, by itself, induce instability. Injury to one ring element, however, should prompt careful scrutiny for a second injury. Any disruption of two or more elements causes ankle instability and can significantly affect the proper functioning of the joint.3

Clinical Features

The presence of immediate swelling and severe pain suggests serious ligament disruption, hemarthrosis, or fracture. Inability to bear weight immediately after an injury often implies a significant pathologic condition.3 Patient recollection of a "pop" sound mandates consideration of ligament, tendon, or retinacular rupture but does not necessarily increase the probability of a fracture. Rapid progression of symptoms may represent more severe injury.

The patient with a subacute or chronic ankle problem may be unable to correlate symptom onset with a particular traumatic event. Inquiry should elicit the type and extent of physical activities and whether the ankle gave way. Finally, ankle injuries or fractures in elderly patients may manifest as subacute problems, which may reflect either misdiagnosis of a

St. Louis, Mosby, 1975; B, modified from the Department of Orthopedics, Mayo Clinic and Mayo Foundation, Rochester, Minn. Reproduced in Storment DM et al: Am J Sports Med 13:296, 1985.)
seriously condition as a simple sprain or neglect by the patient or caregiver.

**Physical Examination**

The examination of the ankle starts with an assessment of deformity, ecchymosis, edema, and perfusion, followed by active and passive range of motion. Assessment of point tenderness may localize ligament, bone, or tendon injuries, particularly when the patient is seen early. Palpation should include the medial and lateral collateral ligaments, the syndesmotic ligaments, the inferior and posterior edges of the medial and lateral malleoli, the entire length of the fibula and tibia, the anterior plafond, the medial and lateral dome of the talus (palpable with the ankle in plantar flexion), the base of the fifth metatarsal, the calcaneus, the Achilles tendon, and the peroneal tendons behind the lateral malleolus. Stress testing of the ankle joint, which is discussed later, should not be performed until a fracture has been excluded. An evaluation of weight-bearing ability should proceed only if clinical suspicion of a fracture is low, the locations of tenderness do not indicate the need for plain radiography, or radiographs have ruled out a fracture.5

**Diagnostic Strategies**

**Radiology**

The anteroposterior, lateral, and mortise views make up the standard three-view radiographic series of the ankle. Although two-view ankle series have been studied, the likelihood of missing a subtle fracture is reduced with three views.4 The anteroposterior view identifies fractures of the malleoli, distal tibia or fibula, plafond, talus dome, the body and lateral process of the talus, and the calcaneus. The lateral view identifies fractures of the anterior and posterior tibial margins, talar neck, posterior talar process, and calcaneus, and any anterior or posterior displacement of the talus. On this view, any incongruity of the articular space between the talar dome and the distal tibia suggests ankle instability, particularly if narrowing of the anterior joint space is present. The lateral view also is useful in identifying an ankle effusion, which appears as a teardrop-shaped density displacing the normal fat adjacent to the anterior or posterior margin of the joint capsule (Fig. 55-5). Its presence suggests the possibility of a subtle intra-articular injury, such as an osteochondral fracture of the talar dome.5

The mortise view, which is taken with the ankle in 15 to 25 degrees of internal rotation, is most important for evaluating the congruity of the articular surface between the dome of the talus and the mortise. The lines formed between the articular surfaces should be parallel and the joint space should appear uniform throughout the tibiotalar and talofibular components of the joint, and the medial clear space should not exceed 4 mm6 (Fig. 55-6).

In most cases of isolated blunt ankle trauma evaluated within 48 hours of injury, the Ottawa Ankle Rules (OAR) should be used to determine whether ankle or foot radiographs are necessary.6 The OAR state that an ankle radiographic series is required if there is pain in the malleolar region with any of the following findings:

- Bone tenderness at the posterior edge of the distal 6 cm or the tip of the lateral malleolus, or
- Bone tenderness at the posterior edge of the distal 6 cm or the tip of the medial malleolus, or
- Inability to bear weight for at least four steps both immediately after the injury and at the time of evaluation

The OAR further state that a foot radiographic series is required if there is pain in the midfoot region with any of the following findings:

- Bone tenderness at the navicular bone, or
- Bone tenderness at the base of the fifth metatarsal, or

---

**Figure 55-4.** The ring structure surrounding the talus is made up of the tibial plafond, medial malleolus, deltoid ligaments, calcaneus, lateral collateral ligaments, and syndesmotic ligaments. The integrity of this ring determines the stability of the ankle. (From Simon RR, Koenigsknecht SJ: Emergency Orthopedics: The Extremities, 2nd ed. Norwalk, Conn, Appleton & Lange, 1987.)

**Figure 55-5.** Lateral radiographic view showing an ankle effusion. The arrows depict the distention of the joint capsule anteriorly (curved arrow) and posteriorly (straight arrow). (From Nicholas JA, Hershman EB [eds]: The Lower Extremity and Spine in Sports Medicine, 2nd ed. St. Louis, Mosby, 1994.)
Inability to bear weight for at least four steps both immediately after the injury and at the time of evaluation

The OAR have a sensitivity approaching 100% in detecting malleolar zone ankle fractures and midfoot zone fractures. The OAR were derived in an adult population and are not applicable in subacute or chronic injuries. The OAR appear to perform well in pediatric patients; however, results have varied, leading some groups of researchers to propose alternative rules to address the unique aspects of this population. The decision rules for foot radiography, although applicable to blunt ankle trauma, apply only to the midfoot zone and only to the mechanism of injury defined by the studies. The OAR were not designed to be general guidelines for foot radiography and certainly do not apply to the hindfoot or forefoot. Finally, the OAR are not applicable to intoxicated patients or those who are difficult to assess because of head injuries, multiple injuries, or diminished sensation related to neurologic deficits. The OAR have been found to have efficacy comparable to that accorded to physician judgment when used by specialized emergency and triage nurses. Although the OAR are well validated, their adoption and application by emergency physicians remain variable.

Other Imaging Techniques

Although plain radiography is the initial imaging modality of choice for ankle injuries, it can miss subtle ankle fractures, osteochondral fractures, stress fractures, or ligamentous injuries. When unexplained symptoms persist after negative or inconclusive findings on plain radiography, other imaging modalities or orthopedic consultation may be advisable on a semiurgent or elective basis.

Radionuclide imaging (bone scanning) can detect soft tissue injuries such as distal syndesmotic disruptions, stress fractures, and osteochondral fractures. Bone scan abnormalities typically appear 1 to 2 weeks before radiographic evidence of a stress fracture, and negative findings on bone scan can effectively rule out the diagnosis. Bone scan abnormalities are nonspecific, however, because infections and tumors also can lead to positive results (see further discussion on stress fracture imaging in the “Foot” section of this chapter), and bone scanning is not useful for follow-up because abnormalities can persist for up to 1 year after recovery.

Computed tomography (CT) scanning provides superior bone imaging and is an excellent modality to delineate abnormalities identified by another imaging modality. CT can detect very small fractures, subtle stress fractures, and ligamentous injuries and can facilitate surgical planning. Newer CT image reformating techniques can be extremely helpful, including two-dimensional multiplanar reformating to identify small fractures, three-dimensional volume rendering to show relationships between tendons and underlying bones, and shaded surface display to provide disarticulated views of joint surfaces and enhance diagnostic accuracy.

Magnetic resonance imaging (MRI) provides unprecedented clarity in depicting soft tissue structures such as ligaments and tendons and also can delineate bone marrow changes associated with stress fractures before radiographic abnormalities appear. MRI can be helpful both in guiding management decisions and in following the patient’s response to therapy.

Additional imaging techniques such as MR or CT arthrography can be useful in the evaluation of chronic ankle pain to detect loose bodies, cartilaginous abnormalities, impingements, or osteochondral defects. The decision to perform specialized imaging of this nature typically is made through orthopedic and radiologic consultations; such studies are not performed in the emergency department (ED).
Ankle Fractures

Pathophysiology. Fractures occur when a deforming force is sufficient to overcome the structural strength of a bone. A bone under tension breaks transversely along the axis of the deforming force.26 (Fig. 55-7). Alternatively, ligamentous rupture or a chip avulsion fracture can occur at either end of a stressed ligament.

Management. The management of ankle fractures consists of identification and classification, assessment of stability, immediate reduction of fracture-dislocations that threaten neurovascular or soft tissue viability, and specific treatment and disposition.

To date, there is no ideal system for the classification of ankle fractures. The classic Danis-Weber (see Fig. 55-8) and Lauge-Hansen classification systems are based on mechanism and fracture location.27 Both systems have limitations, however, and neither accurately predicts clinical outcome in all situations. The Danis-Weber classification has predictive value in unimalleolar fractures, but not in more complex bimalleolar and trimalleolar fractures.28 Moreover, the Danis-Weber system does not adequately classify isolated medial malleolar fractures or pilon fractures.28 By contrast, the Lauge-Hansen classification was intended to characterize ligamentous injury patterns based on the radiographic appearance of ankle fractures. According to a recent MRI study of ankle fractures, however, this system was unable to predict patterns of ligamentous injuries in 53% of cases (26 of 49), and 17% of cases (10 of 59) could not be classified at all.29 This study also found that more than 65% of patients had a complete ligamentous disruption associated with a related malleolar fracture, calling into question the stability of their fracture.29 It is clear that the Lauge-Hansen system is inadequate for classifying ankle fractures and has particular limitations in predicting soft tissue injuries. Modifications to these two classification schemes have been proposed to better describe ankle fractures and, of more importance, to predict outcome.27-29

The injured ankle should be immobilized, elevated, and iced promptly to minimize swelling and further soft tissue damage. The presence of gross deformity with neurovascular compromise or skin tenting necessitates immediate intervention.30,31 Plain radiography before reduction can be helpful but should not be allowed to delay reduction in injuries with vascular compromise.

Appropriate procedural sedation and analgesia techniques should be used for reduction. The fundamental principle of closed reduction is to reverse the deforming forces. For example, reduction of a fracture-dislocation caused by an adduction injury would require an abduction force. The initial application of a distraction force often is helpful. After reduction, neurovascular status should be reassessed, the lower leg should be immobilized and elevated, and postreduction radiographs should be obtained. The overarching goal in the definitive treatment of ankle fractures is to achieve perfect reduction.

Disposition. In general, all displaced or potentially unstable ankle fractures require orthopedic consultation in the ED (Box 55-1). These injuries include all bimalleolar and trimalleolar fractures and unimalleolar fractures with contralateral ligamentous injuries (e.g., a lateral malleolar fracture with deltoid ligament disruption or a medial malleolar fracture with lateral collateral ligament disruption).32 In addition, all intra-articular fractures, especially those with step deformity of the articular surface, require early orthopedic involvement.

Extra-articular fractures that disrupt only one ring element generally can be treated with casting for 6 to 8 weeks. Orthopedic follow-up on an outpatient basis within 1 to 2 weeks of the injury is ideal in case operative intervention is required. The presence of any abnormal measurement on the mortise view (see Fig. 55-6) suggests instability and the need for orthopedic consultation in the ED. Chip avulsion fractures in which the avulsed fragment is less than 3 mm in diameter and minimally displaced can be treated as for an ankle sprain.

The outcome of ankle fractures depends on the extent of injuries, the number of malleoli fractured, ankle stability, and patient age.27,28 For ankle fractures that require surgery, outcome is better in unimalleolar fractures over trimalleolar fractures, in isolated lateral malleolar fracture over isolated medial malleolar fractures, in multimalleolar fractures without medial malleolar fracture over those with malleolar fractures, and in cases with posterior fragments involving less than one third of the articular surface over larger fragments.33

Box 55-1

ANKLE FRACTURES FOR WHICH ORTHOPEDIC CONSULTATION IN THE EMERGENCY DEPARTMENT IS RECOMMENDED

Unimalleolar fractures
  - Displaced medial malleolar fracture
  - Medial malleolar fracture with laterally collateral ligament rupture
  - Displaced lateral malleolar fracture
  - Lateral malleolar fracture with deltoid ligament rupture
  - Lateral malleolar fracture with widened medial clear space

Unimalleolar fracture with syndesmotic diastasis
  - Fibula fracture at or proximal to the tibiotalar joint line
  - Displaced posterior malleolar fracture
  - Posterior malleolar fracture involving more than 25% of articular surface

All bimalleolar fractures
All trimalleolar fractures
All intra-articular fractures with step deformity
All open fractures
All pilon fractures

Figure 55-7. The mechanics of bone failure in tension and types of tension ankle fractures. Arrows indicate the direction of distracting forces. (From Dahners LE: The pathogenesis and treatment of bimalleolar ankle fractures. Instr Course Lect 39[III]:85, 1990.)
Unimalleolar Fractures

Lateral Malleolar Fractures

The stability of an isolated lateral malleolar fracture depends on the location of the fracture in relation to the level of the tibiotalar joint, and the Danis-Weber classification (Fig. 55-8) is useful and predictive of outcome in this type of unimalleolar fracture.26 Fractures below the tibiotalar joint rarely disrupt other bony or ligamentous structures (a Danis-Weber type A1 injury). In the absence of medial injury, lateral malleolar fractures are unlikely to affect the dynamic congruity of the ankle joint.32 The management of uncomplicated lateral malleolar fractures involves casting for 6 to 8 weeks, with no weight bearing for at least the first 3 weeks, and ongoing follow-up to ensure proper healing. Concomitant tenderness over the deltoid ligament, which suggests a biomechanical disruption of both malleoli, an associated fracture of the medial malleolus (a Danis-Weber type A2 injury), or an associated fracture of the posterior malleolus (a Danis-Weber type A3 injury) warrants orthopedic consultation in the ED, especially if the medial clear space on the mortise view is widened (see Fig. 55-6).34

Fibular fractures proximal to the tibiotalar joint line (a Danis-Weber type C injury; see Fig. 55-8) frequently, but not always, disrupt the distal tibiotalar syndesmosis and the medial structures and commonly require orthopedic consultation in the ED. Treatment of an isolated fracture at the level of the tibiotalar joint (a Danis-Weber type B injury; see Fig. 55-8) is controversial because 50% of these injuries are accompanied by an injury to the distal tibiofibular syndesmosis. Distal tibiofibular space measurements on plain radiography have a sensitivity of only 31% and a specificity of 83%, compared with CT scan, in detecting tibiofibular syndesmosis injuries.34 Tenderness on palpation of the syndesmotic ligament or a widening of the medial joint space on the mortise view adds further support to the need for emergency consultation.

Medial Malleolar Fractures

Medial malleolar fractures usually are the result of eversion or external rotation. These two forces exert tension on the deltoid ligament, causing an avulsion of the tip of the medial malleolus or a rupture of the deltoid ligament. Although they can occur in isolation, medial malleolar fractures commonly are associated with lateral or posterior malleolar disruption. Because of this association, the identification of a medial malleolar fracture mandates a careful examination of the entire length of the fibula for tenderness, the presence of which warrants radiographic evaluation to rule out a proximal fibular fracture (Fig. 55-9).

An isolated nondisplaced medial malleolar fracture can be treated with casting for 6 to 8 weeks, with no weight bearing for at least the first 3 weeks, with close orthopedic follow-up. Any displacement or concomitant disruption of the lateral components of the ankle warrants orthopedic consultation in the ED for consideration of operative management.32

Posterior Malleolar Fractures

Isolated fractures of the posterior malleolus are rare and imply an avulsion of the posterior tibiofibular ligament. These injuries can be associated with proximal fibular fractures and medial and lateral collateral ligament sprains. Treatment usually consists of casting for 6 weeks, provided that no associated injury or ankle instability is present.31 Fractures involving more than 25% of the posterior tibial surface usually require open reduction and internal fixation.32

Bimalleolar Fractures

Bimalleolar fractures involve the disruption of at least two elements of the ankle ring and therefore are unstable. These fractures result from adduction or abduction forces, although the latter are more common.26 Rotational injuries also can cause bimalleolar fractures, as well as trimalleolar fractures if the posterior malleolus is involved.

The mechanism of injury often can be deduced from the appearance of the fractures.26 An abduction injury exerts tension on the medial malleolus, causing a horizontal fracture, and bends the lateral malleolus, causing an oblique shear or a comminuted fracture (see Fig. 55-7). An adduction injury causes the reverse, leading to a horizontal fracture of the fibula and an oblique shear fracture of the medial malleolus. A rotational injury causes oblique or spiral fractures of the fibula or medial malleolus. Associated damage to other soft tissue structures (e.g., the syndesmosis) is common with bimalleolar fractures.

Controversy exists about whether such injuries should be treated closed or surgically.26,36 Unstable bimalleolar fractures require surgical intervention, however, and one study found that outcomes at 1 year after surgery were worse with bimalleolar fractures than with lateral malleolar fractures with deltoid ligament disruption.37

Stress fractures of the medial malleolus and distal fibula rarely can be seen in athletes and runners. Plain radiographs

Figure 55-8. The Danis-Weber classification of ankle fractures focuses on the location of the fibular fracture in relation to the tibiotalar joint. See text for explanation. (From Wilson FC: The pathogenesis and treatment of ankle fractures: Classification. Instr Course Lect 39[III]:79, 1990.)
may be nondiagnostic, but radionuclide bone scanning or MRI can establish the diagnosis.38 Most such injuries can be treated nonoperatively, but orthopedic consultation and follow-up are prudent.

Trimalleolar Fractures

Trimalleolar fractures involve fractures of the medial, lateral, and posterior malleoli. Closed treatment of trimalleolar fractures often leads to unsatisfactory results, so operative reduction and internal fixation constitute the treatment of choice.39

Open Fractures

Open ankle fractures usually occur with severe isolated ankle injuries or multiple trauma and require immediate orthopedic consultation. After documentation of the neurovascular status and the extent of soft tissue trauma, the injured leg should be splinted and saline-soaked sterile gauze applied to the wound.30 Swabbing an open wound for bacterial culture and sensitivity testing is unnecessary. If gross deformity is present (indicating a fracture dislocation), immediate reduction before splinting is indicated.30 Tetanus immunization should be administered as appropriate. Because all open fractures are contaminated with bacteria, patients with these injuries should receive intravenous antibiotics.40 For low-energy injuries with mild to moderate contamination, a broad-spectrum cephalosporin usually is sufficient.30,40 Heavily contaminated wounds require the addition of gram-negative bacterial coverage, typically with an aminoglycoside.40 Adding penicillin G as a third antibiotic is necessary for farm- or soil-related crush injuries, where contamination with Clostridium perfringens can be present.40 In addition to the ankle radiographs, radiographs of the foot, tibia, and fibula should be obtained.

All open fractures benefit from early surgical intervention for débridement and thorough irrigation.30 Therefore, identification is crucial, and emergency orthopedic consultation must be sought for such injuries.

Complications. Early operative complications of closed and open ankle fractures include pin site infection, delayed skin necrosis, skin graft rejection, and osteomyelitis. Delayed complications of both operative and nonoperative treatment include malunion, nonunion, osteopenia, traumatic arthritis, chronic instability, ossification of the interosseous membrane, and complex regional pain syndrome.2,41

Pilon Fractures

Pilon fractures involve the distal tibial metaphysis and usually are the result of high-energy mechanisms such as falls from a significant height. These injuries often are comminuted and associated with significant soft tissue trauma, devastation of joint architecture, and leg shortening (Fig. 55-10).

Pathophysiology. Destot first coined the term hammer fracture to describe the way the head of the talus drives itself into the tibial plafond and causes a pilon fracture. The primary deforming force is one of axial compression, and the position of the foot at the time of injury determines the fracture location and pattern42 (Fig. 55-11). Secondary rotational or shear forces may cause increased comminution and fragment displacement with more extensive soft tissue injuries. One fourth of pilon fractures are open, and associated injuries include fractures of the calcaneus, tibial plateau, femoral neck, acetabulum, or lumbar vertebrae, as well as trauma to other major systems.

Management. Radiographic examination should include the entire tibia and fibula, as well as the ankle. The emergency management principles for open fractures, as outlined previously, should be applied. Treatment involves restoration of

Figure 55-9. Maisonneuve fracture. A, Anteroposterior view shows a slight widening (arrows) of the ankle mortise and the medial clear space. Complications. Complications of pilon fractures are common, particularly in more severe cases.43 Early complications include wound infection, skin sloughing, pin site infection, and wound dehiscence. Delayed and late complications include malunion, nonunion, leg shortening, post-traumatic arthritis, avascular necrosis, and protracted pain. Some patients with severe pilon fractures ultimately require arthrodesis.

Soft Tissue Injuries

Ligament Injuries

Ankle sprains are commonly seen in EDs, with a recent series estimating an annual incidence of 52.7 to 60.9 cases per 10,000 population.47 Ankle sprains also are one of the most common injuries in young athletes.48 The term ankle sprain refers to a potpourri of ligamentous and nonligamentous injuries.49 Even when ligamentous injury is certain, the ideal treatment approach remains controversial, and significant variation in clinical practice exists.47,50,51

Pathophysiology. Most ankle sprains occur from extreme inversion and plantar flexion. Usually the anterior talofibular ligament is injured first, followed by the calcaneofibular ligament if the deforming forces are sufficiently strong. Approximately two thirds of ankle sprains are isolated anterior talofibular ligament injuries, whereas 20% involve both anterior talofibular and calcaneofibular ligament injuries. In addition, the lateral
talocalcaneal ligament may be stressed with an inversion injury, leading to avulsion fractures at either end of the attachment sites.\textsuperscript{52} Isolated calcaneofibular or posterior talofibular ligament injuries are rare. Isolated injury of the deltoid ligament occurs in less than 5\% of ankle sprains. Rupture of this ligament occurs most commonly in conjunction with malleolar fractures, especially when an external rotational force is involved.

Injuries of the distal tibiofibular syndesmotic ligaments are uncommon in the general population but may represent 10 to 20\% of injuries in competitive athletes.\textsuperscript{53} Dorsiflexion and external rotation forces usually are responsible for this injury, the presence of which may significantly prolong the recovery time with lateral collateral ligament sprains.\textsuperscript{53}

Ligamentous injuries are classified into three grades based on functional and presumed pathologic findings. A grade I injury involves ligamentous stretching without grossly evident tearing or joint instability. A grade II injury involves a partial tear of the ligament with moderate joint instability, often accompanied by significant localized swelling and pain. A grade III injury involves a complete tear of the ligament with marked joint instability and severe edema and ecchymosis. This classification system, although commonly used, fails to characterize ankle injuries involving two or more ligaments, and it does not consider nonligamentous injuries. These limitations have led to the proposal of other, more comprehensive classification systems.\textsuperscript{52}

Clinical Features. Although desirable, an accurate history of ankle position and injury mechanism often is unavailable. Inversion followed by external rotation of the ankle suggests the potential for deltoid or syndesmotic injury. Forced dorsiflexion with snapping may indicate peroneal tendon displacement. Previous injuries to the same ankle or symptoms of recurrent ankle instability or pain suggest the presence of a subacute or chronic pathologic process.

On physical examination, the presence of edema, ecchymosis, and point tenderness over the medial or lateral collateral ligaments or the syndesmotic ligaments suggests a ligamentous injury. With inversion injuries, point tenderness also may be present along the distal fibula, the lateral aspect of the talus, the lateral aspect or anterior process of the calcaneus, or the base of the fifth metatarsal. Deltoid ligament tenderness demarcates palpation of the full length of the fibula to rule out a proximal fibular fracture (a type C Danis-Weber or Maisonneuve fracture; see Figs. 55-8 and 55-9). The fibular compression test, also known as the squeeze test, reveals fibular and syndesmotic injuries.\textsuperscript{53} To perform this test, the examiner places the fingers over the fibula and the thumb over the tibia at midcalf and squeezes the two bones. The elicitation of pain anywhere along the length of the fibula suggests a fibular fracture or an interosseous membrane or syndesmotic ligament disruption at that location.\textsuperscript{53} Finally, the Achilles tendon should be assessed.

Diagnostic Strategies: Radiology. Standard ankle radiographic views are useful to exclude fractures and to detect instability by the measurement of joint spaces (see earlier discussion and Fig. 55-6).\textsuperscript{5} Presence of avulsion fractures, which can be located at the bases of the malleoli, the lateral process of the talus, the lateral aspect of the calcaneus, the posterior malleolus, the lateral aspect of the distal tibia, or the base of the fifth metatarsal, constitutes an important clue to the location of ligamentous injuries.

In addition to the standard mortise measurements previously discussed, two measurements on the anteroposterior radiograph further evaluate the distal tibiofibular syndesmosis (see Fig. 55-6).\textsuperscript{5} At the distal overlap between the fibula and the tibia, the distance between the posterior edge of the lateral
tibial groove and the medial fibular cortex (syndesmosis A) should not exceed 5 mm.\textsuperscript{6} Furthermore, the amount of tibiofibular bony overlap (syndesmosis B) should be at least 10 mm.\textsuperscript{6} Measurements outside of these values suggest a syndesmotic diastasis.

Stress testing is the application of a deforming force to assess joint motion beyond the physiologic range, the presence of which suggests ligament disruption or mechanical instability. Indications for stress testing are few and may include an acute and severe ankle injury in which rupture of two or more ligaments is suspected; a fracture suspected to be isolated in which the presence of an additional ligament rupture would influence management; the possibility of a concomitant syndesmotic injury; follow-up evaluation of an acute ankle injury after pain and swelling subside; and a chronically symptomatic ankle. With the exception of these scenarios, stress testing is not indicated because it is painful and does not alter management. The normal ranges for stress tests are controversial, so the uninjured side should be examined for comparison.

Common ankle stress tests include the anterior drawer test, the inversion stress test, and the external rotation test. The anterior drawer test primarily assesses the integrity of the anterior talofibular ligament. To perform this test, the patient is comfortably seated, with the knee in 90 degrees of flexion and the ankle in a neutral position or 10 degrees of plantar flexion. The examiner then pulls on the heel with one hand and pushes the leg posteriorly with the other. Anterior displacement of the talus, the perception of a “clunk,” and the induction of a sulcus anteromedially over the joint indicate partial or complete tear of the ligament.

The inversion stress test, or talar tilt test, evaluates both the anterior talofibular ligament and the calcaneofibular ligament. It is performed by inverting the heel with the knee in 90 degrees of flexion and the ankle in neutral position. Palpation of the head of the talus laterally or a finding of increased laxity compared with the uninjured side suggests partial or complete tear of these ligaments.

The external rotation stress test is indicated when injury to the distal tibiofibular syndesmotic ligaments is suspected. It is done by externally rotating the foot with the knee in 90 degrees of flexion and the ankle in neutral position. Pain at the syndesmosis or the sensation of lateral talar motion suggests partial or complete tear of the ligaments.

Stress radiographs, which are radiographs taken during stress testing of the ankle, generally do not influence the emergency management of ankle sprains and are not recommended.\textsuperscript{54} Many injuries can masquerade as ankle sprains.\textsuperscript{49} Box 55-2 lists conditions to be considered in the differential diagnosis; Figure 55-12 shows locations of common fractures in or near the ankle.

Management. Most ligament sprains, regardless of severity, heal well and result in a satisfactory outcome. To date, compelling evidence for a significant difference in outcomes with

surgical and with nonsurgical (functional) treatment is lacking. Limited data suggest that recovery times may be longer and complications more frequent with surgical treatment. Most patients with acute sprains of the ankle should start with functional treatments. For the minority who fail to respond, delayed operative repair of ruptured ligaments, sometimes years after the injury, has been shown to yield results equivalent to those with primary repair.

Functional treatment starts in the ED with RICE therapy (rest, ice, compression, elevation); however, significant variability exists in how this combination is applied, and the optimal methods remain unclear. The evidence to date suggests that lace-up ankle support is more effective in short-term edema reduction than semirigid ankle support, elastic bandaging, and taping. Elastic bandaging causes fewer complications than taping but appears to correlate with slower return to work and sports. A more recent study suggests that compared with elastic bandaging, ankle bracing with a lace-up brace such as the Air-Stirrup Ankle Brace (Aircast, DJO Inc., Vista, California) leads to improved functioning at both 10 days and 1 month.

For grade I or II injuries, short-term protection with a tensor bandage, taping, a laced-up support, or a commercial walking boot or brace, with the optional use of crutches for a few days, is appropriate. For patients with first-time ankle sprains, treatment with a lace-up stirrup brace combined with elastic wrapping results in an earlier return to function compared with use of a brace alone, elastic wrap alone, or a walking cast. For severe grade II or grade III injuries, splinting or casting for up to 3 weeks occasionally is necessary. Because there is no evidence for a more favorable outcome with immobilization than with functional treatment, the use of a lace-up support or air cast that permits some ankle motion generally is preferable. Such patients also should use crutches to avoid weight bearing until they can stand and walk a few steps on the injured ankle without pain. How long crutches will be required varies significantly, ranging from a few days to 2 or 3 weeks. Follow-up care with the patient’s primary physician within the first 2 weeks is appropriate for minor sprains, whereas orthopedic referral on an outpatient basis is prudent for severe sprains.

Analgesics often are necessary for acute pain management in ankle injuries, and studies suggest that nonsteroidal anti-inflammatory agents, acetaminophen, or oral opioids for severe cases are efficacious. Topical diclofenac gel also has been shown to have efficacy in pain reduction.

After the acute management phase, the next two phases of functional treatment involve appropriate early rehabilitation and occur outside the ED. Phase two, which begins after swelling has subsided and the patient is able to bear weight easily, involves strengthening the peroneal and dorsiflexor muscles by isometric, concentric, and eccentric exercises. The final phase begins when full range of motion has been reestablished and the patient can exercise painlessly. This starts with exercises to rebuild motor coordination, recondition the muscles, and increase endurance. The patient uses an ankle tilt board or disk to develop coordination and performs increasingly demanding functional activities (e.g., brisk walking, running, and figure-of-eight running to hopping, jumping, and cutting) to build up the muscle groups. With severe sprains, the patient may benefit from the use of air casts, braces, or taping during the latter two phases of functional treatment. The entire treatment program usually lasts 4 to 6 weeks, depending on the injury’s severity.

Differential diagnosis of a presumed ankle sprain: potential locations of fractures. (From Gustilo RB, et al [eds]: Fractures and Dislocations. St. Louis, Mosby, 1993.)

Tendon Injuries

Achilles Tendon Rupture

Achilles tendon rupture is most common in middle-aged men, and its causes are multifactorial. This condition can easily be misdiagnosed, leading to delay in therapy and a worse prognosis.
Achilles tendon rupture results from direct trauma or indirectly transmitted forces, including sudden unexpected dorsiflexion, forced dorsiflexion of a plantar-flexed foot, and strong push-off of the foot with simultaneous knee extension and calf contraction (as in a runner accelerating from the starting position). Factors predisposing to Achilles tendon rupture include preexisting disease such as rheumatoid arthritis, systemic lupus erythematosus, gout, hyperparathyroidism, or chronic renal failure; steroid use or injection; and fluoroquinolone antibiotic therapy.72,73

The diagnosis of an Achilles tendon rupture is primarily clinical. Patients usually describe a sudden onset of pain at the back of the ankle associated with an audible “pop” or “snap.” Although the pain can resolve rapidly, weakness in plantar flexion persists. On examination, a visible and palpable tendon defect may be noted 2 to 6 cm proximal to the calcaneal insertion in acute presentations but will be less apparent in delayed presentations because of hematoma or edema. Even in cases of complete Achilles tendon rupture, weak plantar flexion may still be possible because of the actions of the tibialis posterior, toe flexors, and peroneal muscles. This retained ability for plantar flexion often leads to the misdiagnosis of ruptures as strains or partial tears.

The classic maneuver to assess the integrity of the Achilles tendon is the Thompson test.74 This is performed with the patient prone and the knee flexed at 90 degrees. Alternatively, the patient kneels on a chair with both knees flexed at 90 degrees and the feet dangling over the edge. Squeezing the calf muscles in these two positions should cause passive plantar flexion of the foot. Absence of this motion or a weakened response compared with the uninjured side suggests complete rupture. Another diagnostic test involves wrapping a sphygmanometer cuff around the calf while the patient is prone. With the knee flexed to 90 degrees and the foot relaxed, the cuff is inflated to 100 mm Hg. Dorsiflexion of the foot by the examiner should cause an increase in pressure to approximately 140 mm Hg. Failure to induce a rise in pressure or a significant diminution compared with the uninjured side suggests rupture.75

Lateral radiographic views of the ankle may confirm rupture by showing opacification of the triangular fatty tissue–filled space anterior to the Achilles tendon (Kager’s triangle) or an irregular contour and thickening of the tendon.76 Ultrasonography or MRI also can demonstrate partial or complete tendon ruptures, but these studies are indicated only in rare cases in which diagnostic uncertainty exists.77 Portable ED ultrasound imaging is occasionally used to confirm the diagnosis, but its accuracy is operator-dependent. The choice of operative repair versus nonoperative management involving a series of casts is controversial.71,77,78 Surgical repair is commonly performed owing to its lower incidence of rerupture, but surgery carries higher rates of other complications such as superficial or deep wound infections in comparison with nonoperative management.77,79 In both types of management, early mobilization improves functional recovery without increasing rerupture rates.77,79 Minimally invasive surgery combined with early rehabilitation facilitates postoperative functional bracing may further improve outcome.80,81 Achilles tendon rupture after initial nonoperative treatment usually necessitates surgical repair. ED orthopedic referral of patients with Achilles tendon rupture is necessary to determine the appropriate management.

Peroneal Tendon Dislocation or Tear

The peroneal muscles are the primary evertors and pronators of the foot and also participate in plantar flexion. The peroneus longus and brevis tendons use the posterior peroneal sulcus (the fibular groove), located behind and underneath the lateral malleolus, as a pulley for their midfoot insertions. The peroneus brevis tendon inserts onto the tuberosity of the fifth metatarsal, and the peroneus longus tendon courses beneath the cuboid to insert onto the medial cuneiform and base of the first metatarsal. The superior peroneal retinaculum (Fig. 55-13), a fibrous structure running from the distal fibula to the posterolateral aspect of the calcaneus, maintains the peroneal tendons against the fibular groove.

Anterior subluxation or dislocation of the peroneal tendons occurs as a result of a tear of the superior peroneal retinaculum attachment from the fibula.82,83 This infrequent injury commonly is misdiagnosed as an ankle sprain and can occur in isolation or concomitant with other sprains or fractures. The mechanism of injury usually is forced dorsiflexion with reflex contraction of the peroneal muscles, resulting in avulsion of the retinaculum and anterior displacement of the peroneal tendons.82

Patients with a peroneal tendon dislocation complain of sudden pain and a snapping sensation over the posterolateral ankle associated with weakness of eversion. Tenderness and swelling over the lateral retromalleolar area (a location not typically involved in ankle sprains) are characteristic. When accurate examination is not precluded by swelling, the dislocated tendons also may be palpable near the inferior tip of the lateral malleolus. Inability to actively evert the foot when it is held in dorsiflexion or frank subluxation of the tendons with this maneuver confirms the diagnosis. Findings on plain radiography are often normal; however, between 15% and 50% of patients will be found to have an associated avulsion fracture of the lateral ridge of the distal fibula. An MRI study or CT scan can be helpful in confirming the diagnosis. All patients with a suspected or confirmed peroneal tendon dislocation should be referred for orthopedic follow-up, because these injuries require surgical repair.83,84 Spontaneous healing is rare in untreated cases, and chronic ankle instability and pain are common sequelae. Peroneal tendons also can tear longitudinally; such injuries manifest either acutely or subacutely with recurrent pain and swelling during activities.84,85

Tibialis Posterior Tendon Rupture

The tibialis posterior is primarily responsible for plantar flexion and inversion along the subtalar joint. Its tendon uses the

posterior surface of the medial malleolus as a pulley and inserts onto the navicular, the medial cuneiform, and the bases of the second through the fifth metatarsals. The peroneus brevis opposes the action of the tibialis posterior. With rupture of the tibialis posterior tendon, the peroneus brevis becomes unopposed and the medial longitudinal arch loses its muscular support, leading to valgus deformity of the hindfoot and a unilateral flatfoot. 86

The mechanism of traumatic tibialis posterior rupture involves forced eversion. 86 In addition to a unilateral flatfoot, pain and swelling on the medial aspect of the ankle are seen. Tenderness is present over the navicular, and the patient cannot perform a toe raise on the affected side. In addition, the patient with a tibialis posterior rupture is unable to invert the foot when it is in plantar flexion and eversion. With a unilateral flatfoot, an observer standing behind the patient can see “more toes” on the lateral aspect of the affected side—a classic sign. 86 Plain radiography can exclude other bone abnormalities. Ultrasonography and MRI are useful imaging modalities to diagnose this condition. 86 Orthopedic consultation is indicated for tibialis posterior tendon ruptures, because surgical repair often is necessary.

Other Tendon Injuries

The tibialis anterior is the primary dorsiflexor of the foot. Its tendon courses under the superior extensor retinaculum and inserts onto the navicular, the medial cuneiform, and the base of the first metatarsal. Tenosynovitis of the tibialis anterior tendon is associated with overuse and characterized by swelling, tenderness, and crepitus along the tendon. Treatment involves RICE therapy, analgesia, and close follow-up. Rupture of the tibialis anterior is rare and often is misdiagnosed as lumbosacral radiculopathy or peroneal palsy because of the footdrop it produces. This condition requires orthopedic consultation in the ED because surgical repair usually is necessary.

The flexor hallucis longus is responsible for flexion of the great toe and participates in plantar flexion of the foot. Its tendon courses behind the medial malleolus through a fibro-osseous canal and inserts onto the distal phalanx of the great toe. Flexor hallucis longus tendinitis, also called dancer’s tendinitis, most often occurs at the fibro-osseous canal. 87 On examination, tenderness and edema posterior to the medial malleolus are noted, and passive extension of the first metatarsophalangeal (MTP) joint causes significant pain when the foot is in neutral position. Initial treatment involves rest, nonsteroidal anti-inflammatory drugs, and a short course of immobilization. Orthopedic follow-up on an outpatient basis should be arranged to ensure proper resolution. Rarely, surgical intervention may be necessary. 87

Ankle Dislocations

Ankle dislocations are described according to the direction of displacement of the talus and foot in relation to the tibia. Thus, dislocation may be upward, posterior, medial, lateral,posteromedial, or anterior. Medial dislocation is the most common. Most dislocations involve associated ankle fractures; rarely, however, dislocations can occur without fracture. The mechanism in all dislocations begins with axial loading of a plantar-flexed foot, which forces the talus either anteriorly or posteriorly from the ankle mortise. The eventual position of the dislocation depends on the position of the foot at the time of injury and the direction of the displacing force. Ankle dislocations can be closed or open and most commonly result from significant falls, motor vehicle collisions, or high-speed

FOOT

PRINCIPLES OF DISEASE

Anatomy

The foot is composed of 28 bones and 57 articulations (Fig. 55-14). It can be divided into three anatomic and functional regions: the hindfoot, which contains the talus and calcaneus; the midfoot, which contains the navicular, cuboid, and cuneiforms; and the forefoot, which contains the metatarsals, phalanges, and sesamoids. The midtarsal joints (Chopart’s joint) join the hindfoot and midfoot, and the tarsometatarsal joints (Lisfranc’s joint) join the midfoot and forefoot. The inferior aspect of the talus has three articulations with the calcaneus that are collectively known as the subtalar joint.

The foot’s bones interlock in a manner that is often likened to the blocks and keystones of a bridge, forming a complex system of arches and beams tethered by ligaments and intrinsic muscles. Extrinsic muscles, originating in the leg, are responsible for most of the foot’s movements, as well as for

---

**Figure 55-14.** Bones and joints of the foot. (From Rockwood CA, et al [eds]: Rockwood and Green’s Fractures in Adults, 3rd ed. New York, JB Lippincott, 1991.)
maintenance of the arch and beam structure. The course and insertion of these extrinsic muscles are important in their actions and in their association with specific avulsions and injuries. The arterial supply to the foot is from the anterior and posterior tibial arteries and the peroneal artery, a proximal branch of the posterior tibial artery. Motor and sensory innervation comes from branches of the deep and superficial peroneal, posterior tibial, saphenous, and sural nerves.

The foot is capable of numerous weight-bearing and non-weight-bearing motions (see Fig. 55-3), which vary at each articulation. Inversion and eversion of the hindfoot occur primarily through the subtalar joint, addiction and abduction of the forefoot through the midtarsal joints, and flexion and extension through the MTP and interphalangeal (IP) joints. The relative importance of specific bones in supporting the body’s weight varies with changes from the static to the mobile state. The biomechanics of walking and running are extremely complex, and significant forces are imparted to the foot’s structures during these precisely coordinated activities.

Clinical Features

An accurate history is essential in the setting of foot trauma because many mechanisms are associated with specific injury patterns. Mechanisms can be broadly divided into direct and indirect (torsional) forces. Falls, twisting injuries, dropped objects, overuse injuries, burns, and penetrating wounds each suggest different potential pathologic conditions. Patient complaints may involve any combination of pain, swelling, deformity, reduced function, or altered sensation. The location of pain, along with a description of its quality, duration, and precipitants, focuses the differential diagnosis. The combination of increasing pain with decreasing sensation is particularly compelling because this may indicate neurovascular compromise requiring immediate intervention. Along with obtaining general information, the history should identify underlying pertinent medical conditions, medications, and previous foot problems.

The structures of the foot are uniquely accessible to palpation and assessment. A directed examination, specific for the patient’s complaint, is most useful in the ED.

If the patient is ambulatory, observation of the gait provides information on the degree of disability and pain and the potential for serious injury. Formal examination begins with observation of the foot in its position of rest, normally one of slight plantar flexion and inversion. Swelling, deformity, ecchymosis, open wounds, color, and temperature should be noted. The use of ecchymosis to localize injuries can be misleading because of pooling of blood in dependent areas after tracking through tissue planes. All patients should have a neurovascular examination with assessment of the dorsalis pedis and posterior tibial pulses, sensation, and motor function. Precise localization of pain or crepitus, when not precluded by swelling, is extremely valuable and facilitates appropriate use of further diagnostic tools. The entire foot should be gently palpated over both the dorsal and plantar surfaces, methodically progressing from the heel to the toes. Particular attention should be paid to areas in which injuries commonly occur, such as the base of the fifth metatarsal.

In some situations, an evaluation of range of motion is indicated. This begins with an assessment of active motion with the foot dependent. Next, if active motion is well tolerated, passive motion is assessed, beginning with the subtalar joint in the hindfoot and moving distally to the midtarsal and forefoot joints. Subtalar motion is evaluated by holding the lower leg with one hand and the heel with the other. Then, with the foot in neutral position, the heel is inverted and everted. Normally, there should be at least 25 degrees of mobility in each direction. Midtarsal motion is evaluated by stabilizing the heel with one hand while the other hand grasps the forefoot at the bases of the metatarsals. The forefoot can then be pronated, supinated, abducted, and adducted. Normally, there should be at least 20 degrees of abduction and 10 degrees of adduction.

Foot motion is evaluated by flexing and extending the MTP and IP joints individually. The first MTP joint has a particularly wide passive range of motion, with 45 degrees of flexion and 70 to 90 degrees of extension. Throughout the physical examination, findings can be compared with those for the opposite foot.

Diagnostic Strategies: Radiology

Plain radiography of the foot may be indicated by history, physical examination, or both. Standard three-view radiographs of the foot consist of anteroposterior, lateral, and 45-degree internal oblique projections. The lateral projection gives the best imaging of the hindfoot and soft tissues, whereas the anteroposterior and oblique projections give the best imaging of the midfoot and forefoot. The numerous overlapping bones of the foot demand this complete radiographic series in all patients for whom radiographic examination is indicated. Injuries to the hindfoot also warrant the addition of standard ankle projections and, when indicated, calcaneal views.

Foot radiographs can be difficult to interpret. Moreover, foot fractures often are minimally displaced, or nondisplaced, increasing the challenge of radiographic diagnosis. Several additional views improve the imaging of specific areas of the foot. Coned views, weight-bearing radiographs, or a 45-degree external oblique projection can be useful, particularly for detection of midfoot and forefoot pathology. The most commonly obtained atypical view is the Harris (axial) view for visualizing the calcaneus and subtalar joints. Special magnification radiographs or stress radiographs also may be useful in selected cases.

Interpretation of plain radiographs can be complicated by the numerous accessory centers of ossification and the presence of sesamoid bones (unipartite and multipartite) that exist as normal variants in up to 30% of the population (Fig. 55-15). The most commonly seen accessory bones are the os trigonum, os tibiae externum (also called an accessory navicular bone), os peroneum, and os vesalianum. These can be differentiated from fractures by their smooth corticated surfaces. Comparison radiographs of the opposite foot may be helpful, although such variants are not inevitably bilateral. Accessory bones themselves can also fracture or cause pain syndromes.

Because of the limitations of plain radiography, other imaging techniques have gained importance for specific foot injuries. Radionuclide imaging (bone scanning) can be useful for evaluating unexplained foot pain or pain in athletic injuries. In the setting of acute foot trauma, this modality often can demonstrate subtle fractures not visible with plain radiography. Bone scanning has been the “gold standard” modality for the diagnosis of stress fractures; however, MRI has comparable sensitivity and better specificity and is emerging as the imaging modality of choice for this diagnosis.

The CT scan can be valuable when complex articulations and overlapping bones make standard radiographs difficult to interpret, particularly in the midfoot and hindfoot. As a result of the wide availability and superiority of CT scanning, plain film tomography is now rarely performed. CT is an excellent modality for imaging complex anatomy, including the subtalar joint, the calcaneus, and the tarsometatarsal (Lisfranc)
joint complex. Three-dimensional CT images provide unprecedented clarity and detail.\(^9\)

MRI has been used in investigation of many of the same fractures and dislocations imaged by CT, and the two modalities can be used in a complementary manner.\(^{100-103}\) As in the ankle, the most significant role of MRI is in delineating soft tissue conditions, such as athletic injuries and tendon ruptures, where it has become the imaging modality of choice. In some conditions involving the ankle joint, MR arthrography can be useful.\(^{104}\)

### SPECIFIC PATHOLOGIC CONDITIONS

This section covers the major fractures and dislocations seen in the foot, progressing anatomically from the hindfoot through to the forefoot. This order corresponds with the sequence of physical examination in patients with foot trauma. Any of these fractures or dislocations may be open, necessitating appropriate wound management.

### Hindfoot Injuries

The hindfoot commonly is involved in foot injuries and is a difficult area to image. Fractures or dislocations in this region can masquerade as ankle sprains and, if not considered in the differential diagnosis, can be missed.

### Talar Fractures

**Principles of Disease: Anatomy.** The word *talus* is related to the Latin *taxis*, meaning “dice,” and dates back to the Roman Empire, when soldiers made dice out of the ankle bones of horses. An appreciation of the unique anatomy of the talus is crucial to an understanding of the pathophysiology and treatment of talar fractures and dislocations. The talus is the second largest tarsal bone and has seven articulations making up 60% of its surface. It is divided into three regions: the head, which articulates with the navicular and calcaneus; the body, which articulates with the tibia, fibula, and calcaneus; and the neck, which joins the head and body and is the only portion of the talus that is predominantly extra-articular. The talus is the only bone in the lower extremity with no muscular attachments and is held in position by the malleoli and ligamentous attachments. The anterior width of the talus is greater than the posterior, causing it to be less stable and more prone to dislocation when the foot is plantar flexed.

The blood supply to the talus is from a vascular ring formed by branches of the anterior and posterior tibial arteries and the perforating branch of the peroneal artery. Vessels enter the talus from three main sites, any or all of which can be disrupted by fractures or dislocations. Because of the tenuous nature of these vessels and the inconsistency of collateral circulation, the risk of avascular necrosis is significant with many talar fractures.

**Pathophysiology.** Talar fractures are the second most common tarsal fracture after the calcaneus. They are best grouped into minor and major fractures, with minor fractures being the more common.\(^{105}\) Stress fractures of the talus also can occur. Minor talar fractures include chip and avulsion fractures of the superior neck and head, and the lateral, medial, and posterior aspects of the body.\(^{106}\) These fractures often involve the same mechanism as that for ankle sprains (see Fig. 55-12 and Box 55-2): a combination of plantar flexion or dorsiflexion and an inversion force. Lateral process fractures, a previously uncommon injury, may be associated with snowboarding and can be occult on plain radiographs.\(^{107}\) Osteochondral fractures of the talar dome also fall into the minor fracture category.

**Major** talar fractures usually are produced by significant forces and occur in the head, neck, or body. Talar head fractures are uncommon, making up 5 to 10% of all talar fractures. Their mechanism is a compressive force applied on a plantar-flexed foot and transmitted up through the talonavicular joint. Comminution is common, and associated navicular fractures can occur, further disrupting the talonavicular articulation.

Talar neck fractures account for 50% of major talar injuries. Their mechanism usually is an extreme dorsiflexion force, as generated in falls or motor vehicle collisions. Associated fractures are common; the most common is an oblique or vertical fracture of the medial malleolus, which is seen in up to one fourth of cases. Other associated injuries include calcaneal fractures and vertebral compression fractures.

Hawkins classified talar neck fractures into three categories (Fig. 55-16): Type 1 fractures are nondisplaced; type 2 frac-
tures show subtalar subluxation; and type 3 fractures, 50% of which are open, involve a dislocation of the talar body from the ankle and subtalar joint. A fourth type that has been added to this classification involves the additional distraction of the talonavicular joint. This classification is important descriptively and because the type of fracture influences both treatment and outcome. Complications are more common with increasing displacement of talar neck fractures.

Talar body fractures include many of the minor talar fractures previously listed. Major talar body fractures are uncommon and usually result from falls with axial compression of the talus between the tibial plafond and the calcaneus.

Clinical Features. Talar fractures range from obvious open fractures to subtle fractures requiring special imaging techniques to diagnose. Typically, a history of a twisting injury, fall, or high-energy impact can be elicited. Dorsal swelling and tenderness over the talus are characteristic findings. Although ankle motion may be preserved, inversion and eversion of the hindfoot often are painful.

Diagnostic Strategies: Radiology. With minor talar fractures, radiographs can be misinterpreted as normal in appearance. Even when supplemental views are obtained, other fractures may be occult on plain radiography and require CT or MRI for visualization. Standard foot and ankle radiographic views usually demonstrate major talar fractures (Figs. 55-17 and 55-18), with the anterior and oblique projections showing talar alignment within the mortise and the lateral projection showing the talar neck and alignment of the posterior aspect of the subtalar joint. Normal variants, such as an os trigonum or os supratibiale (see Fig. 55-15), are occasionally encountered and must be differentiated from fractures. Specialized imaging by CT, or MRI often is required for complete assessment of talar fractures.

Management. Major talar fractures require precise reduction because more weight per unit area is borne by the superior surface of the talus than by any other bone. Most talar fractures involve multiple articular surfaces, and adequate repair often necessitates open reduction and internal fixation. Many minor talar fractures heal with casting, and the initial treatment should be with a non-weight-bearing below-knee cast or posterior plaster slab. Fragments larger than 5 mm in diameter may require excision. Other minor fractures, such as displaced lateral process fractures, require operative fixation because of their articular involvement.

The treatment of major talar fractures is controversial. Any significantly displaced fracture, particularly if associated with neurovascular or cutaneous compromise, requires an early attempt at closed reduction in the ED. Even if nonoperative reduction is impossible, as is common in type 3 and type 4 neck fractures with an intact medial malleolus, alignment often can be improved. With neurovascular or cutaneous compromise, reduction should not be delayed by waiting for radiography or consultation. After appropriate procedural sedation
and analgesia, reduction is performed by grasping the hindfoot and midfoot and applying longitudinal traction with plantar flexion. This is followed by realignment of the foot as reduction is achieved. Posterior slab immobilization and postreduction radiographs should then follow.

Displaced talar head fractures or those involving more than 50% of the articular surface usually require open reduction and internal fixation followed by non-weight-bearing casting. Smaller fragments may require excision. Type 1 fractures of the talar neck usually are treated with non-weight-bearing casting for 8 to 12 weeks. Most type 2 and all type 3 and type 4 fractures require open reduction and internal fixation. The management of talar body fractures varies with location.

**Disposition.** All patients with talar fractures require orthopedic consultation in the ED or referral for early orthopedic follow-up on an outpatient basis. Most minor talar fractures are suitable for outpatient follow-up care.

Although most minor talar fractures heal well, some result in post-traumatic arthritis. Major talar fractures have a high incidence of complications, the most significant of which is avascular necrosis. Outcome depends on the degree of anatomic reduction attained and preservation of the vascular supply. Avascular necrosis can occur and presents treatment challenges. The risk of avascular necrosis increases with increasing talar displacement, ranging from 10% for type 1 neck fractures to 70% or more for type 3 neck fractures. Major fractures of the talar body also are prone to avascular necrosis, the risk of which doubles if an associated dislocation is present. Other potential complications include skin infection, skin necrosis, post-traumatic arthritis, malunion, delayed union, nonunion, and predisposition to peroneal tendon dislocation. The incidence of each complication varies with the type of fracture and the aggressiveness of ED and operative management.

**Osteochondral Fractures of the Talar Dome**

Osteochondral fractures of the talar dome account for 1% of talar fractures and are usually diagnosed late in the clinical course after ankle trauma. These injuries involve both the cartilage and subchondral bone. Many synonyms for this entity, including transchondral fracture, dome fracture of the talus, and chip or flake fracture, are in use. Mechanisms identical to those causing ankle sprains are the most common cause; however, a significant number of these injuries cannot be ascribed to an acute traumatic event.

An osteochondral fracture should be considered in any patient with ligamentous ankle injury accompanied by gross edema and an effusion on plain radiographs. The diagnosis often is missed initially and not made until the patient returns with chronic ankle discomfort. Physical findings usually are nonspecific, although localized tenderness over the posterior-medial aspect of the talus and increasing pain with exertion, weight bearing, or passive plantar flexion may be noted. Standard-view radiographs commonly are normal in appearance or show subtle and easily overlooked abnormalities (Fig. 55-19). Bone scanning is useful in identifying talar dome abnormalities. CT or MRI studies often are required for further evaluation and classification.

When an osteochondral fracture is diagnosed or suspected, outpatient orthopedic referral is advised. The natural history of osteochondral fractures is poorly defined; however, chronic ankle discomfort and osteoarthritis are potential sequelae. Osteochondritis dissecans, a subacute or chronic talar dome defect, may develop after inadequate treatment or failure to treat an osteochondral fracture. In general, however, with appropriate treatment, either by cast immobilization for up to 6 weeks or by excision, the prognosis is good, particularly if treatment begins within 12 months of symptom onset. The benefit of excision, often done arthroscopically, varies with the type of lesion and its location. The previous discussion underscores the necessity for orthopedic evaluation when a patient is seen with persistent unexplained ankle pain after a previous “sprain.”

**Subtalar Dislocations**

**Principles of Disease: Pathophysiology.** Subtalar dislocation, also called peritalar dislocation, is the simultaneous disruption of both talocalcaneal and talonavicular joints without disruption of the tibiotalar joint (Fig. 55-20). This occurs when the talonavicular and talocalcaneal ligaments rupture while the stronger calcaneonavicular ligament remains intact. Subtalar dislocations are rare and are classified by the direction the foot takes in relation to the talus. Anterior and posterior dislocations occasionally occur; however, most subtalar dislocations are either medial or lateral, with medial dislocations accounting for a majority of cases. Dislocation of the calcaneus is an exceptionally rare event that is distinct from subtalar dislocation and involves disruption of the talocalcaneal and calcaneocuboid articulations.

Subtalar dislocations are caused by severe torsional forces such as those generated in motor vehicle crashes or falls. Medial dislocations result from inversion and plantar flexion, whereas lateral dislocations arise from the combination of eversion and plantar flexion. Ten percent of subtalar dislocations are open, and associated fractures are present in one half of the cases, particularly those with lateral dislocations.

**Clinical Features.** Obvious deformity typically is present, often with tension of the skin on the side opposite the direction of dislocation. Neurovascular status should be carefully assessed, although it is rarely compromised. Swelling can mask the extent of the injury, so that diagnosis can be further delayed or missed if only ankle radiographs are obtained.

**Diagnostic Strategies: Radiology.** Although standard foot radiographic views are diagnostic, these may be difficult to obtain because of deformity. Inadequate films due to incorrect patient positioning can delay diagnosis and treatment. The single most helpful radiograph is an anteroposterior view of the foot, which will demonstrate the talonavicular dislocation.

**Management.** Subtalar dislocations require expeditious reduction. More than 80% of closed subtalar dislocations can be
The calcaneus is the largest bone in the foot and the most commonly fractured tarsal bone. It articulates with the talus superiorly (forming the subtalar joint) and with the cuboid anterolaterally.

Pathophysiology. Falls with direct axial compression cause most calcaneal fractures. Because of this high-energy mechanism, associated injuries are common: 7% of calcaneal fractures are bilateral, 25% are associated with other lower extremity injuries, and 10% are associated with spinal injuries, typically vertebral compression fractures.

Numerous classification schemes have been developed for calcaneal fractures. Perhaps the most intuitive is simple categorization of the fracture as either extra-articular or intra-articular. Extra-articular fractures usually involve the addition of a rotatory mechanism and include fractures of the sustentaculum tali and the tuberosity and oblique fractures of the body. Avulsion fractures of the anterior process by the bifurcate ligament (which joins the calcaneus, navicular, and cuboid) also are included in this category. Up to 75% of calcaneal fractures are intra-articular, ranging in severity from nondisplaced single fractures to severely crushed, comminuted fractures. Because of the cancellous nature of the calcaneus, fractures are frequently comminuted. Calcaneal stress fractures may occur as well.

Clinical Features. The typical history is one of a fall resulting in a direct impact on the heel or heels. Physical examination reveals pain, swelling, and tenderness over the affected heel, and weight bearing on the hindfoot usually is impossible. In cases of significant fracture, the heel may be deformed when viewed from behind, appearing short, wide, and tilted. Ecchymoses may extend over the entire sole, a finding not seen in isolated malleolar fractures. The presence of compartment syndrome or associated injuries such as vertebral compression fractures should be considered.

Diagnostic Strategies: Radiology. Standard radiographic views of the foot and ankle should be obtained. The anteroposterior view shows the calcaneocuboid joint and the anterosuperior calcaneus, whereas the lateral view shows the posterior facet and can demonstrate compression of the calcaneal body (Fig. 55-21). In addition, a Harris (axial) view, when not precluded by pain, should be obtained to image the calcaneal tuberosity, subtalar joint, and sustentaculotalar joints. Anterior process fractures require differentiation from a calcaneus secundarius (see Fig. 55-15).

Two assessments are critical to the management of calcaneal fractures: whether the fracture involves the subtalar joint and the degree of depression of the posterior facet. Compression fractures are not always obvious, and measurement of Bohler’s angle (Fig. 55-22) can be helpful. Bohler’s angle is more useful for determining prognosis than diagnosis, however, because the angle may be normal even in the presence of severely comminuted calcaneal fractures. Bohler’s angle is measured on the lateral view as the angle between two lines, one between the posterior tuberosity and the apex of the posterior facet and the other between the apex of the posterior facet and the talus.

In these injuries, which are the end result of the same forces that produce subtalar dislocation, the entire talus is distracted from all of its articulations. Most are open, and infection and avascular necrosis of calcaneus are common complications.  

Total Talar Dislocation

Total talar dislocation is an extremely rare and devastating injury requiring orthopedic consultation in the ED. In these injuries, which are the end result of the same forces that produce subtalar dislocation, the entire talus is distracted from all of its articulations. Most are open, and infection and avascular necrosis of calcaneus are common complications.  

Calcaneal Fractures

Principles of Disease: Anatomy. The calcaneus is the largest bone in the foot and the most commonly fractured tarsal bone. It articulates with the talus superiorly (forming the subtalar joint) and with the cuboid anterolaterally.

Pathophysiology. Falls with direct axial compression cause most calcaneal fractures. Because of this high-energy mechanism, associated injuries are common: 7% of calcaneal fractures are bilateral, 25% are associated with other lower extremity injuries, and 10% are associated with spinal injuries, typically vertebral compression fractures.

Numerous classification schemes have been developed for calcaneal fractures. Perhaps the most intuitive is simple categorization of the fracture as either extra-articular or intra-articular. Extra-articular fractures usually involve the addition of a rotatory mechanism and include fractures of the sustentaculum tali and the tuberosity and oblique fractures of the body. Avulsion fractures of the anterior process by the bifurcate ligament (which joins the calcaneus, navicular, and cuboid) also are included in this category. Up to 75% of calcaneal fractures are intra-articular, ranging in severity from nondisplaced single fractures to severely crushed, comminuted fractures. Because of the cancellous nature of the calcaneus, fractures are frequently comminuted. Calcaneal stress fractures may occur as well.
The navicular has a curved shape—hence the derivation of its name from the Latin navis, “ship.” Because of the navicular’s extensive articular surface, its blood supply can enter only through a small waist of cortex, and the extensive articular surface can develop avascular necrosis. As a result, the navicular is at particular risk for avascular necrosis after fractures, as with the scaphoid bone of the wrist.123

The management of intra-articular or displaced calcaneal fractures is controversial, with many operative and nonoperative approaches described.118,119 If operative fixation is performed, reduction must be as precise as possible to obtain results superior to those with nonoperative treatment. The treatment of nondisplaced extra-articular fractures usually involves casting for 6 to 8 weeks.

Disposition. Intra-articular or displaced calcaneal fractures require orthopedic consultation in the ED. Outpatient orthopedic follow-up care can be arranged for more innocuous injuries, provided that this approach is consistent with local practice and no associated injuries that warrant hospitalization are present. In considering outpatient follow-up, it is important to bear in mind that the extent and severity of calcaneal fractures often are significantly underestimated from plain radiographs. Minor extra-articular fractures usually heal uneventfully; however, with significant calcaneal fractures, complications, including compartment syndrome, are frequent. In both conservatively and surgically treated patients, the incidence of long-term pain, loss of joint mobility, and functional disability approaches 50%.

Midtarsal Joint Injuries

The midtarsal joint (Chopart’s joint) is composed of the talonavicular and calcaneocuboid joints. Injury in this area, although rare, can occur with any ankle, hindfoot, or midfoot trauma. Midtarsal joint injuries usually result from forced dorsiflexion and often are associated with other significant fractures. Sprains, fracture-subluxations and fracture-dislocations, and an isolated “swivel dislocation” (a variant of a subtalar dislocation) all can occur at the midtarsal joint. Pain, swelling, inability to bear weight, and tenderness over the midtarsal joint are usual findings. Although standard radiographs often are abnormal in appearance, the diagnosis frequently is overlooked or delayed, with symptoms ascribed to an ankle sprain (see Fig. 55-12 and Box 55-2). The possibility of a midtarsal joint injury should be considered with any isolated midfoot fracture, particularly those of the navicular tuberosity. MRI can be helpful in the evaluation of midfoot tendon and ligamentous injuries.122 Undisplaced injuries may heal with casting, but operative fixation often is required. Complications are common and include persistent pain, arthritis, and long-term disability.

Midfoot Injuries

The midfoot is an inherently stable region of the foot and is not commonly injured. Fractures and relationships of the midfoot tarsals often are difficult to visualize on standard radiographic views because of underpenetration and the oblique orientation of the bones and joints. A compounding factor is that pain associated with midfoot injuries often is ill-defined and poorly localized. Delay in diagnosis is frequent with midfoot injuries. Although isolated fractures of the midfoot tarsals occur, associated injuries, including significant sprains, subluxations, and spontaneously reduced dislocations, often are present.

Navicular Fractures

Principles of Disease: Anatomy. The navicular has a curved shape—hence the derivation of its name from the Latin navis, “ship.” Because of the navicular’s extensive articular surface, its blood supply can enter only through a small waist of cortex, and the middle third is relatively avascular. As a result, the navicular is at particular risk for avascular necrosis after fractures, as with the scaphoid bone of the wrist.123

Pathophysiology. Navicular fractures, although relatively rare, are the most common midfoot fracture and are classified into dorsal avulsion fractures, tuberosity fractures, and body fractures. Dorsal avulsion fractures account for one half of navicular fractures and usually occur when an eversion stress causes bony avulsion from either the talonavicular capsule or the deltoid ligament. These fractures usually do not involve a significant amount of articular surface. Tuberosity fractures also

Figure 55-22. Boehler’s angle is obtained by measuring the angle formed by two lines, one between the posterior tuberosity (A) and the apex of the posterior facet (B) and the other between the apex of the posterior facet (B) and the other between the apex of the posterior facet (C). A value less than 20 degrees suggests a calcaneal compression fracture. (From Rosen P, et al [eds]: Diagnostic Radiology in Emergency Medicine. St. Louis, Mosby, 1990.)

Boehler’s angle is obtained by measuring the angle formed by two lines, one between the posterior tuberosity (A) and the apex of the posterior facet (B) and the other between the apex of the posterior facet (B) and the apex of the anterior process (C). A value less than 20 degrees suggests a calcaneal compression fracture. (From Rosen P, et al [eds]: Diagnostic Radiology in Emergency Medicine. St. Louis, Mosby, 1990.)
Navicular fractures cause localized tenderness. Standard foot radiographs usually collect this information. The tarsometatarsal joints act to allow supination and pronation of the foot. Lisfranc injuries are classified by the direction of the displacement. Most navicular fractures are suitable for outpatient care; however, significant fractures, particularly if intra-articular, warrant orthopedic consultation. Most Lisfranc injuries are uncomminuted, but a component of dorsal displacement also is commonly present in Lisfranc injuries. The Lisfranc joint is made up of the articulations of the first cuneiform, cuboid, and bases of the second through fifth metatarsals with their respective cuneiforms and navicular. The Lisfranc joint complex is central to an understanding of the Lisfranc joint. The Lisfranc joint complex is a load-bearing structure that allows weight-bearing and propulsion of the foot.
Apparantly trivial fractures, if viewed in isolation, fail to reflect the serious soft tissue disruption that can be present.

The clinical presentation varies with the extent of injury and displacement. Severe pain in the midfoot and inability to bear weight, particularly on the toes, are usual features. Paresthesias occasionally are present, and examination usually reveals edema and ecchymosis. In severe injuries, obvious deformity with forefoot abduction, equinus, and prominence of the medial tarsal area can be present. In addition, anteroposterior shortening and transverse broadening may be found. The dorsalis pedis pulse can be absent, or evidence of vascular compromise of the forefoot may be present. Typically, tenderness along the affected tarsometatarsal joints and pain with passive abduction and pronation of the forefoot are present, sometimes with pathologic mobility.

**Diagnostic Strategies: Radiology.** Standard radiographic views of the foot usually are sufficient to diagnose injuries to the Lisfranc complex (Fig. 55-24). The anteroposterior view identifies fractures and alignment, with the oblique view greatly aiding this assessment by eliminating overlap at the metatarsal bases. The lateral view shows the soft tissues and identifies any dorsal or plantar displacement. When possible, weight-bearing lateral radiographs are obtained because they may be useful to look for flattening of the longitudinal arch in subtle injuries.130 Comparison views are extremely helpful, and a 30-degree oblique view, in addition to the standard 45-degree oblique view, also may be of value. CT scanning can be helpful for diagnosis or to assess severity.

An appreciation of normal radiographic anatomy is essential to assess Lisfranc injuries. Radiographs should be methodically examined, with assessment of alignment, bones, and soft tissues. The first four metatarsals should each line up with their respective tarsal articulation along their medial edge on anteroposterior and oblique radiographic views. The most consistent relationship is the alignment of the medial edge of the base of the second metatarsal with the medial edge of the middle cuneiform. Dorsal alignment of the tarsals with their respective metatarsals should be assessed on the lateral view.

Findings suggestive of a Lisfranc injury include widening between the first and second or second and third metatarsal bases and any fracture around the Lisfranc joint. Fracture of the second metatarsal base (called a fleck sign), cuboid fractures, and cuneiform fractures are particularly common. A fracture of the second metatarsal base is virtually pathognomonic for occult tarsometatarsal joint disruption.

If a suspicious fracture is present and alignment appears normal, a spontaneously reduced dislocation may be present. In addition, plain radiographs may be normal in appearance in the setting of a typical history and tenderness over the tarsometatarsal joints, suggesting a sprain of the Lisfranc complex. In either case, stress radiographs may be diagnostic.

**Management.** Lisfranc injuries usually are treated with closed reduction and internal fixation with percutaneous Kirschner wires. This is followed by non-weight-bearing casting for 12 weeks and wearing of an orthotic for 1 year. Treatment of a Lisfranc “sprain” usually is by immobilization for 6 weeks in a below-knee walking cast.

**Disposition.** Any obvious or suspected Lisfranc injury requires orthopedic consultation in the ED. Patients suspected of having a Lisfranc sprain require casting and orthopedic assessment on an outpatient basis, because operative fixation can be required. The incidence of complications with Lisfranc injuries depends on the timing of diagnosis and the degree of anatomic reduction achieved. Aggressive surgical management clearly improves outcome.

Degenerative arthritis is a common complication of Lisfranc injuries. Other potential complications include compartment syndrome, residual pain, unequal metatarsal pressure, loss of the metatarsal arch, and complex regional pain syndrome. Because of their instability, Lisfranc sprains can result in biomechanical problems if untreated, and delayed presentations pose management challenges and often result in complications.131

**Forefoot Injuries**

Traumatic forefoot conditions are commonly underdiagnosed and often consist of more than one fracture or dislocation occurring simultaneously. As occurs elsewhere in the foot, forefoot trauma may lead to prolonged disability and dysfunction.
Metatarsal Fractures

Metatarsal fractures are common and account for one third of foot fractures. The best approach is first to classify the injury anatomically as occurring in the shaft, the head and neck, or the base. Management is then dictated by the metatarsal involved, the specific location and type of fracture, and the nature of any associated injuries.132

Metatarsal Shaft Fractures

Principles of Disease: Pathophysiology. Metatarsal shaft fractures arise from either direct trauma (e.g., a crush injury from a heavy object) or indirect trauma (e.g., a twisting force applied to a fixed forefoot). Because of the nature of the mechanism of injury, associated phalangeal fractures often occur. Direct trauma may be highly disruptive, resulting in multiple metatarsal fractures and severe complications. The third metatarsal is the most commonly fractured, and metatarsal shaft stress fractures are common.

Biomechanics are an important consideration in the approach to metatarsal shaft fractures. During stance, weight is distributed equally between the heel and forefoot, where it is spread across the metatarsals, with the first metatarsal carrying twice its share of the load. Great toe metatarsal fractures, although uncommon, require more aggressive management because of this load-bearing function. Alignment of fractured metatarsals is important because dorsal or plantar displacement can lead to pain or functional disability by altering the transverse arch and load distribution. Dorsal angulation commonly occurs at the site of metatarsal fractures from the action of intrinsic muscles and toe flexors. Medial or lateral displacement, although less critical, can lead to the development of painful bony prominences or neuromas.

Clinical Features. Metatarsal shaft fractures cause weight-bearing difficulty and tenderness, which usually is maximal on the plantar surface and can be difficult to localize if swelling is significant. Axial compression of the involved toe often is painful, and ecchymosis usually appears within 12 hours of injury. Rotational alignment should be assessed by evaluating the position and plane of the involved digit.

Diagnostic Strategies: Radiology. Standard radiographs are sufficient to diagnose most metatarsal shaft fractures; however, radiographs usually are exposed for visualization of the talar bones, and the forefoot may be overpenetrated. Adjustment of penetration or coned views may be required for visualization of subtle fractures. Displacement and angulation, in both the sagittal and mediolateral planes, should be assessed.

Management. Most undisplaced metatarsal shaft fractures of the second through fifth metatarsals are treated with a below-knee walking cast for 2 to 4 weeks. Early casted ambulation may be beneficial to healing and reduce the incidence of complex regional pain syndrome. Although some practitioners recommend a non-weight-bearing cast for 4 to 6 weeks for

these fractures, others suggest that a metatarsal pad, stiff shoes, and crutches, if needed, are sufficient. These various approaches attest to the fact that most nondisplaced metatarsal shaft fractures heal well regardless of the treatment.

The great toe metatarsal requires more aggressive management because of its biomechanical role and the stresses imposed on it during gait. Nondisplaced first metatarsal fractures should be treated with casting for 4 to 6 weeks. At least the first 3 weeks of this immobilization, if not the entire period, should be non-weight-bearing.

Reduction should be considered in any metatarsal shaft fracture with more than 3 mm of displacement or 10 degrees of angulation. Closed reduction, with toe traps and countertraction at the ankle, often is successful. Non-weight-bearing casting for 4 to 6 weeks should follow. The indications for open reduction are controversial but generally include the presence of compartment syndrome, unstable fractures, open fractures, fractures that have failed closed reduction, and multiple fractures. These are treated with fixation using either Kirschner wires or plates. In particular, displaced first and fifth metatarsal shaft fractures are commonly treated operatively. Major forefoot trauma, with crushing and multiple open metatarsal fractures, requires an aggressive approach with staged operative management.

Disposition. Most undisplaced metatarsal shaft fractures are suitable for management without orthopedic referral. Orthopedic consultation in the ED should be obtained for patients with multiple or displaced fractures. Complications are rare in nondisplaced or minimally displaced metatarsal shaft fractures. Complex regional pain syndrome can occur and may be related to the unnecessary use of non-weight-bearing casting. Inadequate reduction, particularly in the sagittal plane, can lead to biomechanical problems and formation of painful callosities or metatarsalgia. Malunion in the mediolateral plane, particularly if involving the first or fifth metatarsal, can lead to development of pressure points, neuromas, or biomechanical problems. Delayed union, nonunion, compartment syndrome, and soft tissue complications occur uncommonly.

Metatarsal Head and Neck Fractures

Metatarsal head and neck fractures, although similar in their pathophysiology and assessment to shaft fractures, commonly are multiple and often result from direct trauma. Nondisplaced fractures may be treated with a walking cast for 4 to 6 weeks. Often these fractures are displaced, with the distal fragment pulled in a planar and lateral direction by the flexor tendons, a finding best appreciated on oblique and lateral radiographic views. Precise realignment of neck and head fractures is important to maintain the transverse arch. Although reduction may be successful with toe traps, instability is common, and operative fixation is required more commonly than with shaft fractures. Most of these fractures should warrant orthopedic consultation in the ED, particularly if they are displaced or intra-articular. Complications are similar to those seen with shaft fractures.

Metatarsal Base Fractures

Principles of Disease: Pathophysiology. Isolated fractures of the first through fourth metatarsal bases are uncommon. Most are nondisplaced transverse fractures within 1 cm of the tarsometatarsal articulation and arise as a result of direct trauma. An indirect mechanism is more suggestive of the presence of an occult Lisfranc injury. The most commonly encountered metatarsal base fractures occur at the fifth metatarsal.

Fifth Metatarsal. Jones fracture is a term often erroneously applied to any fracture of the fifth metatarsal base. The eponym is in reference to Sir Robert Jones, a physician who in 1902 described a fracture he sustained while dancing and a series of similar injuries. In reality, two distinct fractures can occur in the region of the fifth metatarsal base, and debate continues regarding which one Jones actually described. More important than the terminology, these two fractures differ dramatically in their mechanism, treatment, and prognosis.

The more common and benign fracture at the fifth metatarsal base is of the tuberosity. Also called the styloid, the tuberosity is the bulge of the fifth metatarsal that is easily palpated over the lateral edge of the foot. It is fractured by a sudden inversion of a plantar-flexed foot; for decades, this fracture was thought to be caused by an avulsion at the insertion of the peroneus brevis tendon. Cadaveric studies, however, have implicated the lateral band of the plantar aponeurosis in the location and nature of this fracture. Tuberosity fractures range from tiny flecks to lesions involving the entire tuberosity and usually are extra-articular, although they may extend into the cubometatarsal joint. Often these injuries masquerade as ankle sprains (see Fig. 55-12 and Box 55-2), making the fifth metatarsal base an important area to palpate in any twisting injury.

The more serious acute fracture at the base of the fifth metatarsal is a transverse fracture occurring at least 15 mm distal to the proximal end of the bone. This diaphyseal fracture probably is a true Jones fracture and involves the fourth and fifth intermetatarsal articulations but not the cubo-metatarsal articulation. Diaphyseal fractures result from a complex combination of forces generated when a load is applied to the lateral forefoot in the absence of inversion. Typically, these occur in running and jumping sports. Further subclassification of proximal diaphyseal fractures has been done and can be helpful in determining management.

Clinical Features. The assessment of metatarsal base fractures is similar to that described for fractures of the metatarsal shaft. Pain often is diffuse and difficult to localize in these injuries, with the exception of the easily palpable fifth metatarsal tuberosity. Passive inversion also may be painful with a fifth metatarsal base fracture.

Diagnostic Strategies: Radiology. Standard radiographic views easily demonstrate most metatarsal base fractures. Radiographs should be carefully assessed for fracture angulation, displacement, and articular extension. If the fracture is intra-articular, an estimation of the percentage of articular surface involved is essential in determining management. In difficult cases, CT studies may be helpful.

With fractures of the first through fourth metatarsal bases, it is important to search for other radiologic clues to a Lisfranc injury. A fracture of the second metatarsal base is virtually pathognomonic for occult tarsometatarsal joint disruption. In assessment for a fifth metatarsal base fracture, differentiation between the tuberosity and diaphysis is essential (Fig. 55-25). Care should be taken not to misinterpret an os vesalianum or os peroneum for a fifth metatarsal base fracture (see Fig. 55-15). Standard ankle radiographs also demonstrate the fifth metatarsal base, and this area should be routinely scrutinized.

Management. Nondisplaced extra-articular fractures of the first through fourth metatarsal bases usually are managed with a below-knee cast. Displaced fractures should be reduced and often require fixation. Intra-articular fractures, especially those of the first metatarsal, often lead to complications. Operative fixation may be required, even in nondisplaced intra-articular first metatarsal base fractures, if more than 25% of the articular surface is involved.

The management of fifth metatarsal base fractures depends on the type of fracture. Extra-articular tuberosity fractures, regardless of their size or degree of displacement, heal well
and are managed symptomatically with a walking cast for 2 to 3 weeks, compression wrap, or stiff shoes.\textsuperscript{134} Intra-articular tuberosity fractures involving more than 30\% of the articular surface, or with more than 2 mm of displacement, may require fixation.\textsuperscript{134} Nondisplaced intra-articular fractures usually are treated initially with non-weight-bearing casting for 6 to 8 weeks, followed by radiographic reassessment.\textsuperscript{134} Immobilization for up to 6 months may be required for complete healing, and immediate fixation may be advisable in athletes.\textsuperscript{135} Displaced fifth metatarsal diaphyseal fractures usually are managed operatively, and prolonged treatment may be necessary.

\textbf{Disposition.} Because they are rare and treatment varies, most first through fourth metatarsal base fractures require orthopedic assessment. Nondisplaced extra-articular fractures of the
first through fourth metatarsal bases are suitable for management by orthopedic follow-up on an outpatient basis. Orthopedic consultation in the ED should be obtained in any other first through fourth metatarsal base fracture or if a Lisfranc injury is suspected. Significant or displaced intra-articular fifth metatarsal tuberosity fractures or diaphyseal fractures should warrant orthopedic evaluation in the ED.

Intra-articular metatarsal base fractures involving the first through fourth metatarsals can lead to post-traumatic arthritis requiring arthrodesis. Complications are rare in cases of fifth metatarsal tuberosity fractures, although fibrous nonunion of the fracture fragment can occur. Fifth metatarsal diaphyseal fractures often are complicated by delayed union, nonunion, or recurrence owing to poor healing subsequent to disruption of the metatarsal vascular supply. These complications occur in more than 50% of patients treated conservatively and often require aggressive surgical therapy and prolonged healing times.

Phalangeal Fractures

**Principles of Disease: Pathophysiology.** Phalangeal fractures are the most common forefoot fracture. They usually arise from direct trauma, often the result of dropped heavy objects or stubbing the toe. Less commonly, indirect mechanisms involving twisting of the forefoot can lead to phalangeal fractures. Proximal phalanges are more commonly fractured than middle or distal phalanges, and the proximal phalanx of the fifth toe is most commonly injured. Fractures of the hallux often are displaced, whereas fractures of the lesser phalanges are often comminuted but less commonly displaced.

**Clinical Features.** Although phalangeal fractures generally are considered minor injuries, they can lead to disabling sequelae and merit careful assessment. The patient with a phalangeal fracture has acute pain and swelling of the affected toe, often with difficulty ambulating or wearing shoes. Examination may reveal tenderness, crepitus, and reduced range of motion. A subungual hematoma often is present if the distal phalanx is involved, and open fractures are common.

**Diagnostic Strategies: Radiology.** Standard radiographic views usually are sufficient to demonstrate phalangeal fractures, with the lateral view being most sensitive. Often the uninjured toes must be positioned out of the way to obtain adequate radiographs, and magnification radiographs occasionally are required. Angulation and joint involvement should be assessed.

**Management.** Most phalangeal fractures are easily managed and heal well. A subungual hematoma should be evacuated, and nail bed repair may occasionally be required. Nondisplaced lesser phalangeal fractures should be stabilized by “buddy taping”—splinting the injured toe to an adjacent toe with adhesive tape. Placement of gauze between the splinted toes is advisable to prevent skin maceration. Phalangeal fractures often remain painful for 2 to 3 weeks until stabilized by callus.

If significant displacement or angulation is present, reduction should be performed with manual traction or toe traps after digital block anesthesia. Moderate persistent angulation or displacement is acceptable if the clinical appearance of the toe remains satisfactory. Rarely, operative fixation of lesser phalangeal fractures is indicated, particularly in cases with severe rotatory deformity or in open fractures requiring débridement.

Nondisplaced phalangeal fractures involving the hallux are treated by buddy taping, with a walking cast worn for 2 to 3 weeks if the toe is painful. Alternatives to standard casting techniques, such as the slipper cast, have also been described for phalangeal fractures. Displaced phalangeal fractures of the hallux require reduction. If the reduction is inadequate or unstable, operative fixation may be indicated. Unless completely nondisplaced, most intra-articular fractures involving the hallux are treated with operative fixation, although this is an area of controversy.

**Disposition.** Most phalangeal fractures do not require orthopedic evaluation; however, if displacement persists or causes cosmetic or functional concern, consultation is advised. Orthopedic consultation in the ED is advised for poorly reduced or intra-articular hallux fractures.

Complications of phalangeal fractures are uncommon. With intra-articular phalangeal fractures, particularly those involving the hallux, arthritis may be a late sequela, or fragments may require operative removal. Symptomatic angular malunion and osseous deformity can occur with phalangeal fractures, and exostectomy is sometimes required.

Sesamoid Fractures

The sesamoids are two flat oval bones found within the tendon of the flexor hallucis brevis, under the head of the first metatarsal. Their name comes from the Greek word *sesamoeides*, meaning “resembling a sesame seed.” Ten percent of the population has sesamoid bones under the fifth metatarsal head, and uncommonly, sesamoids are found under the second, third, or fourth metatarsal (see Fig. 55-15). Sesamoid fractures are uncommon and usually are caused by direct trauma from falls. Hyperextension of the great toe can indirectly lead to a sesamoid fracture. Sesamoid fractures also can be found in association with MTP joint dislocations. The medial sesamoid is more commonly fractured than the lateral, and a suspected fracture must be differentiated from partition of sesamoids, which occurs in up to one third of the population and also is more common on the medial aspect. Stress fractures of the sesamoids also occur. Sesamoid fractures generally require a below-knee walking cast for 3 to 4 weeks. Most heal without complications and do not require orthopedic consultation.

Metatarsophalangeal Dislocations

**Principles of Disease: Pathophysiology.** Dislocations of the MTP joint are uncommon injuries because of the protection footwear provides and the inherent stability of MTP and IP joints. MTP joint dislocations can occur in any joint and in any direction. First MTP joint dislocations require large forces and usually result from motor vehicle collisions. These injuries often are open and typically involve dorsal dislocations of the distal component caused by hyperextension of the MTP joint. Associated sesamoid fractures may be present. Complex dislocations, in which the sesamoids or local tendons prevent closed reduction, can occur. Second through fifth MTP dislocations usually are medial or lateral displacements that occur when the toe strikes or hooks an object. The most common is a lateral dislocation of the fifth MTP joint.

**Clinical Features.** Dislocations of the MTP joint cause pain, swelling, and difficulty bearing weight on the ball of the foot. First MTP joint dislocations usually are obvious on clinical examination because the toe is angulated upward with dorsal and proximal displacement of the proximal phalanx. This deformity leads to a striking prominence of the metatarsal head over the plantar surface. Skin tenting or a dimple may be present. Rarely, the sesamoids are palpable dorsal to the metatarsal, indicating a complex dislocation. Dislocations of the lesser toes often are more subtle in presentation, and comparison with the uninjured foot may be helpful. Neurovascular compromise is rare.
Dislocations of the MTP joint are well visualized on standard radiographic views of the foot. In first MTP joint dislocations, a double density often is present, caused by superimposition of the base of the proximal phalanx over the metatarsal head. Radiographs should be scrutinized for signs suggesting complex dislocation, such as the sesamoids lying between the two articular surfaces or dorsal to the metatarsal head.

**Management.** Most MTP joint dislocations, particularly of the lesser toes, are easily reduced with longitudinal traction. Appropriate analgesia or local anesthesia should be administered before reduction is attempted. Dorsal dislocations of the first MTP joint can be more challenging and may require initial accentuation of the deformity during reduction. Joint stability should be assessed and repeat radiographs obtained after reduction of an MTP joint dislocation. After reduction, a walking cast with a toe plate is worn for 3 weeks, followed by physiotherapy to ensure adequate range of motion. Alternatively, buddy taping and an aluminum splint can be used for immobilization.

**Disposition.** Most MTP joint dislocations can be managed without orthopedic consultation. If crepitus or obvious instability is present or postreduction radiographs show joint incongruity or an intra-articular fracture, orthopedic consultation should be obtained for possible fixation. First MTP joint dislocations that are open, show radiographic evidence of complexity, or do not easily reduce require orthopedic consultation in the ED, because open reduction may be required. Very rarely, MTP joint dislocations of the lesser toes require open reduction.

Complications are uncommon after MTP dislocations. Arthritis and reduced range of motion, particularly of the hallux, may occur. Dislocations for which the diagnosis is delayed for more than 3 weeks often are not amenable to closed reduction and may require metatarsal head excision.

### Interphalangeal Joint Dislocations

IP joint dislocations are much less common than MTP joint dislocations and are sometimes overlooked. Most IP joint dislocations occur in the great toe and are a result of axial loading. IP joint dislocations usually involve dorsal displacement of the distal component and are easily managed without orthopedic consultation. Reduction is performed with longitudinal traction after digital block anesthesia is obtained. Initial accentuation of the deformity may be necessary if reduction is unsuccessful with simple traction. If the dislocation involves the great toe, a walking cast with a toe plate for 3 weeks is indicated after reduction. Lesser toes require only buddy taping. As with the MTP joint, complex dislocations involving the first IP joint can occur, and orthopedic consultation in the ED for open reduction may be necessary. Very rarely, lesser toe IP joint dislocations are irreducible with closed methods and will require open reduction.

### Foot Pain

**Perspective.** Foot pain, particularly in the absence of obvious trauma, poses a diagnostic and therapeutic challenge. Plain radiographs commonly are normal in appearance, so that the history and physical examination assume increased importance. Although a definitive diagnosis often is difficult to obtain in the ED, a structured approach aids in appropriate patient management and disposition. Most causes of foot pain are minor and self-limited, but the possibility of serious pathologic conditions (e.g., infection, arthritis, tumor) must be considered. Although orthopedic consultation in the ED is rarely required, orthopedic follow-up on an outpatient basis is indicated for selected cases.

Foot pain can be classified as acute, acute on chronic, or chronic and is best approached anatomically by localizing symptoms to the hindfoot, midfoot, or forefoot. Three conditions warrant specific mention.

**Complex regional pain syndrome** is a condition involving pain in the presence of trophic changes and vasomotor instability from inappropriate sympathetic nervous system activity and was previously termed “reflex sympathetic dystrophy.” Complex regional pain syndrome occurs months after trauma, which may be major, as in a Lisfranc injury, or relatively innocuous. It has many synonyms, including causalgia and Sudeck’s atrophy, and produces pain of a diffuse burning, aching, or searing nature, together with evidence of vasomotor instability. Complex regional pain syndrome should always be considered in the differential diagnosis for foot pain after trauma.

Another important consideration in patients with previous penetrating trauma is a retained foreign body. Foreign bodies can be a source of chronic drainage or chronic pain. The inciting trauma may have occurred years previously, and a history of the event may be difficult to extract, or such an event may be unknown to the patient.

Finally, stress fractures are an important consideration in the differential diagnosis for foot pain, particularly in athletes.

### Hindfoot Pain

Hindfoot pain is a common complaint that usually is the result of overuse rather than acute trauma. Bone pain in the hindfoot necessitates consideration of talar or calcaneal stress fractures. A calcaneal stress fracture may be suspected when pain is elicited on squeezing the calcaneus mediolaterally. Another cause of bone pain is impingement by an os trigonum (see Fig. 55-15) or prominent lateral posterior talar process. The *os trigonum syndrome* involves pain during plantar flexion of the foot and is particularly common in ballet dancers. A bone scan may be required for diagnosis, and treatment is surgical.

Most patients with hindfoot pain describe subcalcaneal heel pain, a complaint with an extensive differential diagnosis. The literature on this topic is conflicting and fraught with inconsistent terminology. The most common causes of subcalcaneal pain are plantar fasciitis, subcalcaneal bursitis, acute rupture of the plantar fascia, and nerve compression.

The plantar fascia is a tough layer of the sole that is functionally significant during foot strike and the early stance phase of walking. Plantar fasciitis, an overuse injury of insidious onset, usually begins with pain on first weight bearing in the morning or after prolonged sitting. This progresses to persistent pain during gait. Pain and tenderness are localized to the medial aspect of the heel. Plantar fasciitis is particularly common in cavus feet, although the nature of this association is unclear. Plain radiography is not diagnostic but shows a calcaneal spur in 50% of patients with plantar fasciitis. This is a stress-related ossification with a 16% incidence in asymptomatic persons and is not considered the primary cause of pain in plantar fasciitis. Rarely, fascial ossification (an os subcalcis) may be seen.

Plantar fasciitis is distinct from subcalcaneal bursitis, a condition with an identical presentation in which the pain is localized to the bursa directly below the calcaneus. Differentiating these two conditions can be difficult and usually is academic, because initial treatment is identical: a combination of avoiding precipitating conditions, rest, padding, orthotics, and nonsteroidal anti-inflammatory drugs. Shock wave therapy can be beneficial in refractory cases. Very rarely, surgical release of the plantar fascia is required, a therapy that can be beneficial in either condition.
Plantar fascial rupture is a tear of the origin of the plantar fascia at the calcaneus. This injury usually occurs during the push-off phase of gait. Swelling may be noted, and typically pain is elicited by passive dorsiflexion of the hallux. Treatment is nonsurgical, often with a period of cast immobilization for symptomatic relief.

Compression of either the abductor digiti quinti nerve or the posterior tibial nerve (the so-called tarsal tunnel syndrome) can cause subcalcaneal heel pain. Diagnosis of these conditions is difficult and is sometimes facilitated by assessing the impact of selective nerve block with local anesthesia. Initial treatment of these conditions is similar to that for plantar fasciitis, although local steroid injections or surgical release may be required. Other nerve entrapments also can occur in the hindfoot area.

Many tendons course through the hindfoot, particularly the anteromedial aspect, and tendinitis can occur. Other tendon pathologic conditions (e.g., ruptures, dislocations, retinacular injuries) must be considered because they can result in significant functional disability.

Midfoot Pain
Isolated midfoot pain is less common than forefoot or hindfoot pain. Stress fractures are uncommon in the midfoot and most commonly involve the navicular. Other causes of midfoot pain include symptomatic accessory bones, particularly the os tibiale externum or os peroneum (see Fig. 55-15). An os tibiale externum is present in up to 14% of the normal population and is asymptomatic in most cases. This accessory bone can produce debilitating pain on the medial aspect of the midfoot. A bone scan facilitates diagnosis, and surgical excision may be necessary. An os peroneum is one of several conditions that can cause lateral plantar pain in the midfoot region. Localization of tenderness is aided by resisted plantar flexion, and treatment ranges from immobilization to surgical excision.

Forefoot Pain
The forefoot is the site for a myriad of painful problems. Bunions, painful bursae, blisters, corns, calluses, hammertoes, and ingrown toenails all are diagnostically obvious but can pose therapeutic challenges. Many are the result of poor footwear or a biomechanical problem with the foot and respond to appropriate padding, avoidance of precipitants, and occasionally surgical intervention.

Metatarsalgia is an often used, although loosely defined, term referring to pain in the region of the metatarsal heads. This is a common presenting complaint with many potential causes. Metatarsal stress fractures are extremely common and must be considered in the differential diagnosis for any unexplained forefoot pain. Flexor or extensor tendinitis also can produce metatarsal area pain and is suggested when plain radiographs show areas of tendinous calcification. Arthritis, sesamoiditis, or a sesamoid stress fracture should be considered when pain occurs in the area of the hallux. “Turf toe” is MTP joint inflammation of the hallux resulting from repeated hyperextension stress. It usually responds to symptomatic measures.

An important cause of unilateral metatarsalgia is a perineural fibrosis of the intermetatarsal plantar digital nerve, more commonly known as Morton’s neuroma. This neuropathy of unknown cause was first described in 1876 and usually involves the second-third or third-fourth inter-metatarsal space, causing lancinating pain with weight bearing. The pain may be associated with paresthesias and can radiate into the toes. In addition, “afterburn” pain can persist during rest. The pain of Morton’s neuroma is reproduced when structures of the affected interspace are pinched or when the metatarsal heads are compressed together. Hence, pain may occur intermittently with tight-fitting footwear (e.g., rock-climbing shoes, ski boots). Crepitus or a nodule may be palpable. Treatment usually involves surgical excision or neurolysis.

Freiberg’s disease is an osteochondrosis of the metatarsal head, usually involving the second metatarsal, and is another cause of pain in this area. Ingrown toenails are a common affliction that can occur in any toe, most commonly the hallux. Often the abnormality is perpetuated by short nail trimming, which affords the opportunity for a spicule of nail to grow under the nail fold. Allowing the nail to grow out and providing local care usually will lead to resolution of the condition. Antibiotics are indicated if infection is present. Chronic or recurring ingrowth necessitates partial or complete excision of the nail and germinal ablation.

### SPECIAL CONSIDERATIONS

#### Stress Fractures

**Principles of Disease: Pathophysiology.** Stress fractures can occur anywhere in the appendicular skeleton but are particularly common in the lower extremity. Athletic activities, particularly running, account for most stress fractures. Predisposing factors include training errors, poor footwear, a previous period of inactivity, or a change in running surface. Anatomic variations may play a role, with cavus feet being more prone to stress fractures than flat feet.

Pedal stress fractures may occur anywhere but are most common in the second or third metatarsal shaft. It is not generally appreciated that calcaneal stress fractures occur almost as often as metatarsal stress fractures. Midfoot stress fractures are uncommon and usually occur in the navicular. The type of sport or activity is related to the location of stress fractures, with navicular stress fractures most often seen in basketball, metatarsal shaft stress fractures in running, and fifth metatarsal diaphyseal stress fractures in football.

**Clinical Features.** Although the history is variable, most stress fractures produce localized pain of insidious onset, usually with aching over a period of weeks. The pain may be anywhere in the hindfoot, midfoot, or forefoot but is most common along a metatarsal. Initially symptoms occur after athletic activities, but later they limit such activities. Often a predisposing factor, such as a training regimen change, is present. A menstrual history should be obtained in female patients because amenorrhea, often a result of training, can predispose to stress fractures.

Physical examination may reveal swelling, point tenderness, or percussion tenderness. In most patients, however, these findings are absent, and the diagnosis must be suspected by history alone.

**Diagnostic Strategies: Radiology.** Initial plain radiographs are commonly normal because bone reaction in stress fractures depends on the length of time from symptom onset. Radiographic abnormalities in the metaphyses can take up to 4 weeks to develop, and those in the diaphyses can take 6 weeks. Although plain radiographs have low sensitivity for stress fractures, their specificity is high. The three important findings are periosteal new bone, endosteal thickening, or a radiolucent line. Radiographic findings vary with location: Metatarsal fractures usually show callus or periosteal reaction, whereas navicular fractures show a lucent line, and calcaneal fractures show curvilinear sclerosis.

The diagnosis of a stress fracture is easily missed because only 50% of patients develop plain radiographic abnormalities. Until recently, radionuclide bone scanning was the imaging modality of choice for stress fractures. Bone scans are nonspecific but extremely sensitive for stress fractures, usually
Compartment syndrome typically causes pain -

**PART II**

**Trauma**

**Orthopedic Lesions**

Vascular

Crush such as claw deformity. Tendon injuries associated with innocuous - because apparently minor injuries can lead to complications. An attempt should be made to repair any tendon transection, because apparently minor injuries can lead to complications such as claw deformity. Tendon injuries associated with innocuous lacerations are easily missed if not carefully sought. Splinting for 2 to 6 weeks is required after tendon repair.

**Contusions and Sprains**

Contusions of the foot, usually from dropped objects, are a common injury. Sprains can occur in the foot, particularly with athletic injuries. The calcaneocuboid and intermetatarsal ligaments are common sites of injury. Localizing such injuries is difficult, and these are often diagnoses of exclusion made after appropriate clinical and radiographic assessment. Both contusions and sprains usually respond rapidly to symptomatic therapy. Sprains of the Lisfranc joint complex are unique and require orthopedic consultation in the ED.

**Tendon Injuries**

Acute tendon ruptures in the foot, apart from the Achilles and posterior tibial tendons, are rare. Although isolated ruptures of the flexor hallucis longus and anterior tibial tendons have been described, most tendon transections are the result of lacerations. These typically arise from one of two mechanisms: penetrating wounds to the sole of the foot or major trauma from such sources as dropped objects, lawn mowers, or motor vehicle crashes. Plantar penetrating trauma usually results in flexor tendon injuries, whereas most major mechanisms involve extensor tendons.

Orthopedic or plastic surgery consultation in the ED is indicated for any patient known or suspected to have a tendon injury in the foot. It is clear that flexor and extensor hallucis longus tendons should be repaired primarily; however, the need to repair other tendons is controversial. In general, an attempt should be made to repair any tendon transection, because apparently minor injuries can lead to complications such as claw deformity. Tendon injuries associated with innocuous lacerations are easily missed if not carefully sought. Splinting for 2 to 6 weeks is required after tendon repair.

**Crush Injuries, Amputations, and Major Vascular Injuries**

Rapid assessment, stabilization, and immediate consultation are priorities in the ED management of a major crush injury, amputation, or vascular injury of the foot. The injured limb must be handled gently and can be irrigated with sterile saline solution to remove debris. Use of other irrigating solutions, exploration, or débridement is contraindicated. Antibiotics should be administered, as with any open fracture. Compartment syndrome must always be considered. Many factors enter into surgical decision-making for patients with such injuries, and objective measures such as the “mangled extremity score” have been developed to predict the need for amputation. Local crush injuries often heal better than diffuse crush injuries. A surgical goal is preservation of as much length as possible to maintain a longitudinal arch. In the presence of a major vascular injury, the likelihood of permanent disability is high.

**Compartment Syndrome**

**Principles of Disease: Pathophysiology.** Compartment syndrome is defined as an increase in pressure within a confined osseofascial space that impedes neurovascular function, resulting in tissue damage.

Compartment syndrome in the foot, as elsewhere in the body, constitutes a medical emergency. Classically, four foot compartments—medial, central, lateral, and intersosseous—are described, although studies using dye injection have suggested that there may be as many as nine foot compartments.

Pedal compartment syndrome is most commonly caused by significant crush injuries, fractures, or dislocations. Other causes include bleeding disorders, burns, postischemic swelling after arterial injury or thrombosis, drug or alcohol overdose, excessive exercise, and venous obstruction. Damage is related to the duration and magnitude of compartment pressure rise and the arteriovenous gradient. Compartment syndrome can develop anywhere from 2 hours to 6 days after an insult, although the peak incidence is at 15 to 30 hours.

**Clinical Features.** Compartment syndrome typically causes pain out of proportion to that expected for the injury. The pain is not decreased by immobilization and can be described as a feeling of tautness within the foot. In the case of calcaneal fractures, the pain often is a relentless burning involving the entire foot. Physical examination may reveal tense swelling and sensory deficits. Pain is exacerbated by any movement (active or passive) that stretches the muscles of the involved compartment. Passive dorsiflexion of the toes often is painful. Peripheral pulses and capillary refill usually are normal in compartment syndrome and thus offer no reassurance when present. Presence of an open wound does not guarantee that all compartments are decompressed.

**Diagnostic Strategies: Special Procedures.** The only way to diagnose a compartment syndrome is to measure intracompartamental pressure. The decision to perform this maneuver relies on appropriate clinical suspicion. Techniques of pressure measurement are well described, with a pressure greater than 35 mm Hg generally considered diagnostic. Compartment syndrome can occur at lower pressures in hypotensive patients. The needle localization and distinguishing of foot compartments is challenging because of their small size. For this reason and because of its importance in surgical decision-making, measurement of pedal compartment pressures usually should be left to an orthopedic surgeon.

**Management.** Early identification and prevention of further tissue damage are important considerations in any patient with a mechanism consistent with the development of compartment syndrome. Circumferential bandages and casts should be avoided during early management. In diagnosed or suspected cases of compartment syndrome, the limb should be positioned at the level of the heart. Limb elevation beyond...
this point is contraindicated because it would decrease arterial flow, thereby narrowing the arterial-venous pressure gradient.

Disposition. If compartment syndrome is suspected, immediate orthopedic consultation is indicated because the only treatment is decompressive fasciotomy.

**KEY CONCEPTS**

- Ankle dislocations with skin tenting or neurovascular compromise should be reduced promptly, before radiographs are obtained.
- The entire fibula should be examined if an isolated medial malleolar fracture is present, to rule out a proximal fibular (Danis-Weber type C or Maisonneuve) fracture.
- Before diagnosis of an ankle sprain, other injuries that may mimic an ankle sprain should be ruled out.
- Patients with Achilles tendon rupture are still capable of weak plantar flexion. The Thompson test should always be performed if an Achilles tendon rupture is suspected.
- The presence of accessory ossicles may explain unexpected radiologic “lesions” in the foot.
- The possibility of a Lisfranc injury should always be considered with any fracture or dislocation in the tarsometatarsal region, particularly fractures of the second metatarsal base.
- The tuberosity should be carefully differentiated from the diaphysis in all fifth metatarsal base fractures.
- The possibility of a stress fracture should always be considered in patients with long-standing foot pain, particularly if symptoms are in the metatarsal region.
- Compartment syndrome of the foot can occur, with potentially devastating results if it is not diagnosed early.

The goals of emergency wound treatment are to restore function, repair tissue integrity with strength and optimal cosmetic appearance, and minimize risk of infection. Risk of infection depends on the location, mechanism, host, and care. The risk for a clean facial wound produced by incision is less than 1%, whereas a dirty crush injury to the lower extremity may have more than a 20% risk. Wound infection generally results in delayed healing, decreased strength, and a poor cosmetic result. These facts highlight the need for high-quality wound care. Understanding the biology of wound healing and the technical aspects of wound treatment facilitates emergency management of these patients.

Emergency physicians must also be aware of the medicolegal risk associated with soft tissue injuries. Including injuries to the hand, wound-related complaints are the fourth most common cause of malpractice claims against emergency physicians. Missed foreign body, wound infection, and missed tendon or nerve injury are the most common complications leading to these claims.

**PRINCIPLES OF DISEASE**

**Anatomy of Skin and Fascia**

An understanding of skin anatomy leads to better appreciation of wound closure concepts and techniques. The skin is a complex organ that protects the body against bacterial invasion and ensures thermoregulation. The skin also helps to regulate water content and register sensory stimuli.

The skin and fascia vary in thickness from 1 to 4 mm, depending on the part of the body. The epidermis, the outermost layer, is several cell layers thick. The most important parts of the epidermis are the stratum germinativum (basal layer), where new cells originate, and the stratum corneum, the outermost cell layer that gives the skin its cosmetic appearance. The layer of skin directly beneath the epidermis is the dermis. The much thicker dermis is primarily composed of connective tissue. The dermis is the key layer for the ultimate healing of skin wounds. Optimal healing and minimal scar formation depend on the removal of debris and devitalized tissue from the dermis. The dermis also functions to anchor sutures placed percutaneously or subcutaneously.

The superficial fascia lies directly beneath the dermis and encloses the subcutaneous fat. This space must be irrigated and débrided to decrease the risk of infection. The deep fascia lies beneath the fat and is a strong, off-white sheath that covers and protects the underlying muscles and helps prevent superficial infection from spreading to deeper tissues. The deep fascia must be closed to maintain its protective and functional roles.

**Wound Biology**

Normal wound healing is a well-choreographed sequence of biologic events. It is described as an orderly process, but it actually represents multiple phenomena that seem to occur simultaneously. These events include coagulation, inflammation, collagen metabolism, wound contraction, and epithelialization. Maintaining the balance of these events is crucial for normal healing. Delaying any of the stages may result in a weak closure and dehiscence. Prolonging segments of the process may affect the ultimate scar appearance.

Soon after tissue integrity is altered, the process of coagulation begins. Platelet release factors initiate and enhance a response from inflammatory cells. Capillary permeability increases to allow white blood cells to migrate into the wound. Neutrophils and monocytes act as scavengers to rid the wound of debris and bacteria. Monocytes transform into macrophages, which seem to have a major role in subsequent healing phenomena. In addition to providing wound defense, macrophages release chemotactic substances, calling on other monocytes to stimulate fibroblast replication and trigger neoangiogenesis.

Collagen is the principal structural protein of most tissues of the body. Normal tissue repair depends on collagen synthesis, deposition, and cross-linking. Fibroblasts synthesize and deposit collagen compounds 48 hours after injury. Immature collagen is highly disorganized because it exists in a gel-like consistency.

After a series of enzymatic processes, characteristic fibrils are produced. Subsequent intermolecular cross-links are responsible for a major portion of the strength of the collagen fibril. The entire process depends on tissue lactate and ascorbic acid and is directly related to tissue arterial carbon dioxide partial pressure. In the absence of vitamin C, prolyl and lysyl hydroxylase do not activate, and oxygen is not transferred to proline or lysine. Underhydroxylated collagen is produced, and characteristic collagen fibers are unable to form. Wound healing is poor, and capillaries are fragile. Without oxygen to hydroxylate proline and lysine, a local condition resembling scurvy tends to occur.
Under normal conditions, collagen synthesis peaks by day 7, coincident with rapid increases in tensile strength. The healing wound has the greatest mass at 3 weeks but remodels itself during the next 6 to 12 months. However, the wound achieves less than 15 to 20% of its ultimate strength by 3 weeks and only 60% by 4 months.3

Wound contraction is the movement of whole-thickness skin toward the center of the skin defect. Immediately after injury, the wound edges retract and increase the size of the defect. Normal skin tension along the lines of minimal tension produces this retraction (Figs. 56-1 and 56-2). Wounds perpendicular to these lines are under greater tension and result in a larger scar.1,4

During the next 3 or 4 days, the wound size shrinks as its edges move toward the center. This phenomenon is independent of epithelialization, and the presence of collagen is not necessary for it to occur. This process is considered beneficial to healing and should not be confused with contracture that results from scar shortening.1,3

Contracture becomes more apparent when the normal healing process is prolonged. The effect is a disfiguring hypertrophic scar. Optimizing the duration of the inflammatory phase and minimizing wound tension help to produce a more “appealing” scar.1,4

Epithelialization is a mechanism in the healing process whereby epithelial cells migrate across the wound. Mitosis appears at the wound edge near the basal cell layer within hours of injury. Eschar or other debris impedes this process. When a wound is properly cleansed and débrided and kept moist and protected, epithelialization proceeds at a maximum rate.3

In a surgically repaired laceration, epithelialization bridges the defect by 48 hours. The new tissue proceeds to thicken and grow downward, beginning to resemble the layered structural characteristics of uninjured epidermis within 5 days. Simultaneously, keratin formation loosens the overlying scab.

**Biomechanical Properties of Skin**

Various forces (lines of tension) exist as a result of skin elasticity from collagen fibers. These static forces may vary more than fivefold with the respective area of body skin surface, but the static tension of a given area of skin remains constant. These static forces are shown clinically by the gaping of wounds after incision. The magnitude of static skin tension is directly related to ultimate scar width.1,4

Uneven, jagged wounds have greater surface area than do linear lacerations. The skin tension is distributed over a greater area and is less per unit length of tissue. Meticulous reapproximation of the jagged edges results in a more appealing scar. Sharp débridement, converting a jagged wound to a linear laceration, is often unwise because it may cause too much tissue loss and produce a wider, more visible scar.4

Skin forces produced by muscular contraction and movements of flexion and extension influence healing and scar size. These dynamic forces are greatest where skin elasticity is necessary for function. Lacerations parallel to skin folds, lines of expression, and joints do not impair function or produce unattractive scars. Wounds that traverse the skin lines heal with conspicuous scars and may impair function.4 Knowledge
of these lines and forces is necessary for optimal wound repair. In addition, the patient should be educated about wound healing and scarring potential.

### CLINICAL FEATURES AND DIAGNOSTIC STRATEGIES

#### History

A detailed history should be obtained as part of routine wound evaluation. Serious complications can result when basic information is not obtained. If the patient has significant peripheral vascular disease, is immunocompromised, or has a high risk of retained foreign body, wound care decisions may be changed. Essential historical information includes medical history, mechanism and setting of injury, and tetanus status.

#### Risk Factors

Risk factors for wound morbidity include prolonged time since injury; crush mechanism; depth of the wound; age of the patient; high-velocity missiles; and contamination with saliva, feces, soil, or other foreign matter (Box 56-1). Three hours after acute trauma, bacteria proliferate to a level that may result in infection. Standard wound care guidelines for the routine wound recommend closure within 8 to 12 hours of injury. Yet all risk factors must be considered before adopting specific timeline guidelines, and flexibility is required. Lacerations produced by fine cutting forces resist infection better than crush injuries. Reduction of blood flow to wound edges in the latter may increase the infective concentration of bacteria by 100-fold. High-velocity missile injuries produce bacteria by 1011 per gram wet weight) that greatly exceeds the numbers needed to produce infection ($>10^6$ bacteria per gram tissue).

The presence of any foreign matter in the wound decreases resistance to infection. Soil fractions, which include organic components and inorganic clay particles, damage host defenses with adverse interactions between charged soil particles and white blood cells. The presence of these soil fractions greatly increases the infective potential of bacteria.

Optimal physical assessment of wounds requires patience, diligence, and an organized approach. Wound closure decisions must be individualized for each laceration. Sharp, clean lacerations of the face may be safe to close up to 24 hours after the time of injury, whereas highly contaminated blunt injuries to the feet should never be closed primarily. When the distal neurovascular evaluation is completed, the examination may proceed. All of these risk factors have to do with the injury, but there are three additional areas of concern: (1) immunocompetence of the host, (2) physical characteristics of the host (e.g., peripheral vascular disease), and (3) structural defects that invite bacterial seeding (e.g., damaged or prosthetic heart valves).

#### Physical Examination

Physical examination errors are minimized with optimal visualization and anesthesia. When the injury occurs on an extremity, use of a sphygmomanometer may help to ensure a bloodless field. The blood pressure cuff is placed proximal to the injury, and the extremity is elevated above the heart for at least 1 minute. Exsanguinating the extremity may be hastened by wrapping the limb tightly with an Ace bandage, beginning distally and ending at the base of the cuff. The sphygmonomanometer is inflated to a pressure greater than the systolic pressure of the patient. Although this process causes the patient significant discomfort after 1 minute, the cuff can safely remain inflated for 2 hours. A Bier block should be used if inflation longer than several minutes is contemplated.

A thorough examination of the wound requires that the tissues be adequately anesthetized. Subcutaneous tissues quickly reapproximate after injury, giving the appearance of a shallow wound. In addition, significant subcutaneous swelling lends to this appearance and renders examination of the laceration more difficult, as in wounds of the scalp and face. Careful probing and examination are needed to avoid missing damage to structures deep to the skin and subcutaneous tissue. This warning is more crucial for wounds on the distal aspects of upper and lower extremities. Finger lacerations are rarely gaping, but crucial structures (e.g., tendons, nerves, and vessels) are often damaged. The examiner must pry the wound margins apart, ensure a blood-free field, and examine the tissues as the digit or extremity is placed through range of motion. The injured section of tendon may have been in a different state of tension and in a more proximal or distal location at the time of injury. Wounds that cannot be explored adequately and wounds with probable trauma to underlying tissues or with foreign matter require additional studies. It may be appropriate to extend the laceration to enable improved visualization of wound depth and extent.

Sterile gloves may not be a necessary part of wound closure. Although data are limited, one study found that the use of sterile gloves makes no difference with respect to the incidence of infection. Clean nonsterile gloves should be worn to offer some protection for both the patient and the provider.

#### Foreign Body Assessment

No single method can guarantee the identification and removal of all foreign matter from wounds. The key is to document all efforts and to explain to the patient the possibility of a foreign body. Good follow-up can protect the patient as well as the health care provider.

---

**BOX 56-1  RISK FACTORS FOR WOUND INFECTION**

1. Injury >8–12 hours old (varies depending on the following factors)
2. Location: leg and thigh, then arms, then feet, then chest, then back, then face, then scalp
3. Contamination with devitalized tissue, foreign matter, saliva, or stool
4. Blunt (crush) mechanism
5. Presence of subcutaneous sutures
6. Type of repair: risk greatest with sutures > staples > tape
7. Anesthesia with epinephrine
8. High-velocity missile injuries
Attempts to visualize foreign matter by standard radiography are not as helpful as might be expected. The radiodensity of an object depends on the relative density of the matter and the adjacent tissue. Pieces of glass greater than 1 mm thick are visible when appropriate views are ordered. Many organic substances, such as wood, are not visible on plain films, but specifically requested soft tissue views may increase the yield. A radiolucent shadow may be seen on close inspection because the foreign substance displaces tissue in its path. Xerograms are better than plain radiography but still miss some plastics and organic matter. A computed tomography (CT) scan is excellent for identifying all foreign substances but is expensive and results in significant exposure to radiation. Ultrasonography is a good technique, but the small size of many foreign bodies and pockets of air, edema, pus, and some calcifications may produce confusing echoes, limiting its clinical utility. When simpler, standard methods fail to locate a foreign body that is likely or definitely present, ultrasonography or a CT scan should be considered.

### MANAGEMENT

#### Anesthesia

After an appropriate neurovascular examination is documented, the involved tissue should be anesthetized. Careful physical examination and thorough cleansing, irrigation, and débridement require that the patient be free of pain. Regional anesthesia may be preferable for wounds innervated by one superficial nerve. Injections at the wound site produce swelling and further distortion of landmarks. With a regional block, more than one laceration may be repaired in the same nerve distribution without additional anesthesia. Lacerations on the face, hands, fingers, feet, and toes in the mouth are often well suited for regional anesthesia.

#### Anesthetic Agents

Lidocaine (Xylocaine) is the most common agent used for local and regional anesthesia. It is safe and fast acting. Onset of action for direct infiltration occurs within seconds and seems to last 20 to 60 minutes. When lidocaine is administered as a regional nerve block, onset occurs in 4 to 6 minutes and generally lasts 75 minutes, although it may remain effective for 120 minutes. A 1% lidocaine solution contains 10 mg/mL. It is safe to use 3 to 5 mg/kg, not exceeding 300 mg at a single injection. More volume can be added safely every 30 minutes. When epinephrine is added, the resulting vasoconstriction prolongs the effect for 2 to 6 hours and the safe dose is increased to 5 to 7 mg/kg. However, the addition of epinephrine has been shown to delay healing and lower resistance to infection. Lidocaine with epinephrine should be avoided in wounds with higher risks of infection and when tissue viability is of concern.

Traditional teaching has been to avoid epinephrine with careful screening epinephrine can be safely used in digital blocks. Digital artery vasoospasm, accidentally induced by local injection of epinephrine, can be reversed successfully with a local injection of 0.5 to 2 mg of subcutaneous phentolamine or by applying topical nitroglycerine.

Bupivacaine (Marcaine) provides anesthesia that is equal to that of lidocaine. Onset of action is slightly slower than that of lidocaine, but the duration of anesthesia is four to eight times longer. These benefits suggest that bupivacaine is the preferred local anesthetic agent for the care of most wounds. In adults, the maximal reported safe dose is approximately 2.5 mg/kg without epinephrine and 3.5 mg/kg with epinephrine. The dose can be repeated every 3 hours, not exceeding a total of more than 400 mg in a 24-hour period. The maximal intraoral dose is 90 mg.

Local injection of lidocaine should be done with a 27-gauge needle; the slower the injection, the less pain produced. The rate of injection through a 30-gauge needle is far too slow, and the thin needle is difficult to control. A 25-gauge needle is acceptable, but the more rapid injection can result in greater patient discomfort. The needle should be introduced through the cut margin to minimize the pain of the injection. Concerns of spreading bacteria into the adjacent uninvolved tissue and increasing the frequency and severity of wound infections are unfounded. The pain of injecting lidocaine can be ameliorated with the addition of bicarbonate to buffer the solution. The shelf life of the lidocaine-bicarbonate mixture decreases but it remains effective for 1 week at room temperature and for 2 weeks if refrigerated. Adding sodium bicarbonate in a 1:10 volume ratio to lidocaine (1 mL bicarbonate and 10 mL lidocaine) decreases the pain of injection without compromising the quality of anesthesia. A much smaller dose of bicarbonate must be added to bupivacaine because the alkalization results in precipitation. A 1:100 volume ratio (0.1 mL of bicarbonate and 10 mL of bupivacaine) has been found to be effective. Warming the anesthetic solution is also an effective means of decreasing the pain of injection.

Topical anesthesia may be an effective painless alternative. Studies show that a combination of tetracaine, adrenaline (epinephrine), and cocaine (TAC) (0.5% tetracaine, 1:2000 adrenaline, and 11.8% cocaine) can function effectively on skin lacerations. The solution is administered by soaking a cotton ball with 5 mL of the combined drugs (25 mg of tetracaine, 25 mg of adrenaline, and 590 mg of cocaine) and applying it to the wound for 10 to 20 minutes. TAC is similar to infiltrative lidocaine in all respects, including risk of complications. It is more effective on the face and scalp than on extremities. Data suggest that half-strength TAC solution is effective and may reduce the potential for toxicity. The tetracaine component may be superfluous and can be eliminated without compromising the quality of anesthesia. By using a topical combination, time to repair is reduced, patient acceptance improves, and landmarks are left undisturbed. Although experimental studies show that TAC increases the infection rate in contaminated wounds, this is not the case with routine wound care. The proven benefits and enhanced patient compliance, especially in pediatric patients, make TAC an excellent medication to use alone or in conjunction with another local anesthetic. The potential toxicity from TAC has been documented by (1) measurable plasma cocaine levels and (2) a case report of a child’s death from exposure to TAC. The child’s wound was on the upper lip between the vermilion border and the nares. The solution apparently dripped onto the nasal and oral mucosa, increasing the systemic absorption of the drugs. Until further studies are done, TAC should be avoided in the repair of highly contaminated wounds and in lacerations near mucous membranes. In children, a half-strength solution can be used to reduce potential toxicity.

The potential serious adverse effects of TAC have led to the increasing use of other topically applied anesthetic combinations. A mixture of lidocaine (1–4%), epinephrine (1:2000), and cocaine (0.5–2%) has been used successfully in place of TAC. This mixture avoids the untoward side effects of cocaine. EMLA (eutectic mixture of local anesthetics) is a cream used to produce anesthesia of wounds. Although the onset of anesthesia is longer than for the other mixtures (1 hour vs. approximately 30 minutes), one study showed that the...
need for supplemental local anesthesia was reduced. Because the time to onset is greatly delayed with EMLA, its utility may vary with emergency department patient volume.

A newer technique that uses topical anesthesia in a progressively layered approach appears to be safe and effective. Although time to anesthesia was significantly longer (a mean of 29 minutes compared with 5 minutes), efficacy was equivalent. Patient satisfaction was much greater with the layer topical approach, and the elimination of the risk of a hollow-bore needle puncture is a major benefit.

**Allergy**

Allergy to local anesthetics is uncommon. Two distinct groups of “caine” anesthetics exist. The esters include procaine, tetracaine, and benzocaine. The second group, including lidocaine and bupivacaine, belong to the amide family. Allergy to the esters is uncommon. True allergy to agents in the amide family is rare. Good history taking is the best way to document a true allergic reaction. Many patients labeled as allergic have suffered uncomfortable drug effects or autonomic responses to the amide family, and can be used for wound anesthesia when there is concern about potential allergic reactions.

When allergy to a local anesthetic is known or strongly suspected, alternatives are available. No cross-reactivity occurs between the amide and ester families, so an agent from a different group may be chosen. Single-dose vials of lidocaine or cardiac lidocaine are not mixed with methylparaben and may be used. A test dose of 0.1 mL may be administered intradermally before proceeding. The patient should be observed for 30 minutes, and as with any allergy testing, the emergency physician should be prepared to treat all complications. Aqueous diphenhydramine (1%) has also been shown to provide effective local anesthesia.

**Skin Preparation**

Disinfection of the skin (not the wound itself) may be accomplished with several different agents. The ideal agent is fast acting, has a broad spectrum of antimicrobial activity, and has a long shelf life. Povidone-iodine (Betadine) and chlorhexidine (Hibiclens) satisfy all three characteristics. Although excellent as skin disinfectants, both products are toxic to wound defenses and may increase the incidence of wound infection. Povidone-iodine is effective against gram-positive and gram-negative bacteria, fungi, and viruses. Chlorhexidine is less effective against gram-negative bacteria, and its efficacy against viruses is unknown. Care must be taken to avoid spilling these substances into the wound. Exposure of the eye to these agents can be disastrous. Chlorhexidine has been shown experimentally and in case reports to produce serious permanent corneal opacification.

Body, facial, and head hair is usually removed to clean and examine the wound, although this is not necessary to diminish the risk of wound infection. Removal of the hair makes it easier for the patient to keep the area clean and ultimately facilitates accurate suture placement and removal. Exceptions are parts of the body where hairlines provide important landmarks for the accurate reapproximation of tissue margins, most notably the eyebrow. Reports of inconsistent or absent eyebrow hair regrowth suggest that eyebrow hair should not be shaved.

Surgical studies show that hair removal with a razor is three to nine times more likely to result in a wound infection than is clipping the hair. It seems that the razor damages the infundibulum of the hair follicle. The wounded follicle provides access for bacterial invasion and ultimately infection. For wounds considered to be at high risk of infection, clipping may be done with electronic shears or scissors because close shaving is not necessary. Another option is to apply a petroleum-based product to the hair adjacent to the wound margins, allowing the provider to keep the hair away from the surgical field.

**Wound Preparation**

**Débridement**

Débridement is the removal of foreign matter and devitalized tissue from the wound. With respect to ultimate wound healing and risk of infection, débridement is the most important consideration in wound care. The presence of any devitalized tissue in the wound delays healing and significantly increases the risk of infection. However, the benefits of débridement have to be weighed against the consequences of producing a larger tissue defect. The resultant closure is exposed to higher tension and may result in a wider scar. Skin edges that are clearly devitalized must be débrided before wound closure. On the trunk, where there is little concern for specialized tissue, wide excision and débridement are feasible. On the face and hands, where all tissue must be saved if possible, the process is more difficult. Meticulous sharp excision of small fragments of nonviable tissue should be performed only by experienced physicians. When the viability of large areas of skin or muscle is a significant concern, the wound should be prepared for delayed primary closure.

**Wound Cleansing**

An ideal wound cleanser has broad antimicrobial activity with a rapid onset. It is nontoxic to the tissue and does not reduce tissue resistance to infection, delay healing, or decrease the tensile strength of the healing wound. Many antiseptic solutions have been used clinically and studied in great detail (Table 56-1). Much debate exists regarding which agent comes closest to possessing these qualities. Povidone-iodine in various concentrations, saline, and, more recently, tap water have received the most attention.

Evidence suggests that a 0.9% normal saline solution or tap water may be effective irrigants when used with high-pressure syringe irrigation. Saline is the traditional wound-irrigating fluid of choice. However, tap water has consistently produced equivalent rates of infection and cosmetic outcomes. Tap water irrigation allows a large volume of irrigation rapidly and inexpensively and is especially suited to upper extremity and scalp injuries.

Free iodine, although possessing broad, rapid antimicrobial activity, is too toxic to tissue and its defenses to have therapeutic value in the open wound. An iodophor is a complex of iodine with a carrier to increase its solubility and decrease the availability of free iodine. The most widely used iodophor is povidone-iodine, in which the carrier molecule is povidone (formerly polyvinylpyrrolidone). It is generally available in a 10% solution, which is 1% free iodine. The clinical benefit of this complex is a solution that maintains broad antimicrobial activity and eliminates most local and systemic toxicity. It is well documented that even a 5% povidone-iodine solution is toxic to polymorphonuclear neutrophil leukocyte activity and

Wounds close to the eye, where pressure irrigation may it is safe, effective, requires no preparation, and is less expen- soon may become the preferred method of irrigation because ap water irrigation cial, it seems that the key to cleansing is high-pressure irriga- be allowed to contaminate open wounds.

Simply soaking the wound in an antiseptic solution is not of ridding the wound of bacteria and debris outweighs this risk. 37,38 Although several commercial devices are available, attaching an 18-gauge needle to a 35-mL syringe yields a force of 7 or 8 psi. High pressures of 50 to 70 psi may be obtained by using a commercial water pick. These pressures may cause some tissue damage, but the beneficial effect of ridding the wound of bacteria and debris outweighs this risk. Simply soaking the wound in an antiseptic solution is not beneficial and may be harmful. Scrubbing the wound with a sponge with large-pore cells inflicts tissue trauma and impairs the ability to resist infection. Tissue damage can be decreased by using a sponge with a fine size of pore cell. Adding a surfactant further minimizes the mechanical trauma inflicted by the sponge. Flooding the wound under low pressure using a bulb syringe or gravity alone does not reduce the incidence of infection, regardless of the agent used.

At least one study has shown little benefit to any irrigation in facial and scalp lacerations. This study prospectively compared outcomes of almost 2000 immunocompetent patients. Infection rates and cosmetic outcomes were similar in the irrigation and the nonirrigation groups.39

Irrigation

The quality of mechanical cleansing is one of the most impor- tant determinants of wound prognosis. The most effective form of wound cleansing is high-pressure irrigation. Irrigating with pressures greater than 7 pounds per square inch (psi) significantly decreases the number of bacteria and the incidence of infection.37,38 Although several commercial devices are available, attaching an 18-gauge needle to a 35-mL syringe yields a force of 7 or 8 psi. High pressures of 50 to 70 psi may be obtained by using a commercial water pick. These pressures may cause some tissue damage, but the beneficial effect of ridding the wound of bacteria and debris outweighs this risk. Simply soaking the wound in an antiseptic solution is not beneficial and may be harmful. Scrubbing the wound with a sponge with large-pore cells inflicts tissue trauma and impairs the ability to resist infection. Tissue damage can be decreased by using a sponge with a fine size of pore cell. Adding a surfactant further minimizes the mechanical trauma inflicted by the sponge. Flooding the wound under low pressure using a bulb syringe or gravity alone does not reduce the incidence of infection, regardless of the agent used.

At least one study has shown little benefit to any irrigation in facial and scalp lacerations. This study prospectively compared outcomes of almost 2000 immunocompetent patients. Infection rates and cosmetic outcomes were similar in the irrigation and the nonirrigation groups.39

often the best method for deciding when it is safe to close a wound. In one study in which hand wounds were described as dirty, 22% became infected. When the injury was documented to be clean, the incidence of infection was 7.1%.39

Three wound closure options are available. The wound may be (1) closed primarily in traditional fashion, (2) closed in 4 or 5 days (delayed primary closure) or (3) left open and allowed to heal on its own. Delayed primary closure is a safe alternative to traditional primary closure.40 Overall healing time is not affected, and the risk of infection is greatly decreased if proper technique is used. When a wound is slated for delayed primary closure, it must be prepared, débrided, and irrigated in the same manner as for immediate closure. The wound should be packed to prevent it from closing on its own. If the wound is on an extremity, the injury should be splinted and dressed, and appropriate wound care instructions should be given. The patient should return for a wound check and packing change in 24 hours and should be instructed to follow up in another 72 hours for definitive repair, with wound closure 96 to 120 hours after injury. No studies offer guidelines for prophylactic antibiotic use when delayed primary closure is the treatment option. Extrapolation from other wound studies strongly suggests that antibiotics offer no benefit.

Individuals who do not seek medical care after an injury select the option of leaving a wound open to heal on its own. Most patients who present to an emergency department with a laceration undergo some form of wound closure. Yet one study that examined unsutured hand lacerations less than 2 cm long followed patients for 3 months and found that there was no significant difference in cosmetic appearance, and there was no difference in time to resume activities of daily living.41,42

Closing a wound loosely is occasionally discussed as an option in the treatment of contaminated wounds. This choice should rarely be considered. The loosely closed wound approximates the tissue margins enough to allow the wound to seal itself completely within 48 hours. The infection risk when using this method is the same as when closing the wound traditionally.

Wound Tension

The goal of wound closure is optimal anatomic and functional reapproximation of tissue with minimal risk of complication. Consideration must be given to the wound’s size, shape, location, depth, and degree of tension. Wounds with high static and dynamic tension that require meticulous closure cannot be closed with tape or staples. Delicate approximation of wound edges under tension can be accomplished only with suture.

Several techniques may be used to reduce wound tension. Deep sutures may be placed in subcutaneous tissue to help bring the wound margins closer together. In this manner, forces on the skin are reduced, and potential dead space can be closed. Care should be taken to avoid suturing adipose tissue because it may become necrotic and increase the likelihood of infection. The number of dermal sutures depends on the characteristics of the wound. Generally, the number should be kept to a minimum because suture material acts as foreign matter in the wound and can increase the risk of infection. Subcutaneous sutures should never be placed in the hand or foot because of the major structures that reside near the surface. Another method of ameliorating static tension from cut edges of the wound is to undermine at the lacerated margin. Undermining helps free the dermis from its deeper attachments, allowing the skin edges to be approximated with less force. Care must be taken to preserve the blood supply to the wound margins and not increase dead space in the process.

Suture Technique

Careful surgical technique is important to optimize the ultimate repair. If possible, pickups, hemostats, or forceps should not be used, especially on wound margins. Blind clamping in a wound can damage a nerve, artery, or tendon. Wound margins should be everted and the sutures tied just tightly enough to allow the edges to approximate lightly. The edges can be everted by ensuring that the needle enters and exits perpendicular to the skin. Wounds with opposing margins of different thickness can be difficult to close. If this difference is not considered and corrected, the ultimate scar has uneven margins that cast a shadow on the skin and is unsightly. To close these wounds, the needle should be pulled through the cut margin of one side before entering the opposite edge. This method gives the emergency physician the best opportunity to take an equivalent amount of tissue on both sides of the wound. Viable edges of a jagged wound must be meticulously reapproximated. Because of the greater surface area and the ultimate contraction of the wound, preserving the jagged edges results in a more “natural” scar.

Basic and Advanced Techniques

Simple Sutures. Wound closure with simple interrupted sutures is the most common method of laceration repair in emergency departments. The placement of simple sutures yields excellent cosmesis and a low infection rate.

Procedure. The needle is placed to one side of the laceration margin and enters the skin at approximately 90 degrees. To pass the needle through the tissue, the clinician’s wrist is supinated and guides the needle deep but parallel to the skin surface. Wrist supination is extended as the needle exits the skin on the opposite side perpendicular to the surface. Proper technique produces wound edges that are slightly everted and are lightly touching. The art of the process takes into consideration swelling while being careful not to secure the suture too tightly because necrosis of the wound margin tissue can seriously compromise healing.

Intradermal (Buried) Sutures. Placing cutaneous sutures in wounds under tension can lead to ischemia of the wound margin and an unsightly scar. Proper placement of buried intradermal sutures helps to approximate dermal margins and reduce wound edge tension. Buried sutures should not be used in contaminated wounds because they increase the risk of wound infection. Sutures through adipose tissue also increase infection and do not relieve skin tension.

Procedure. Placement of buried sutures differs from traditional suturing because of the need to bury the knot deep to the skin. Failure to do this can interfere with dermal healing and can leave a small lump under the surface of the skin. The needle is introduced deep in the wound in the subcutaneous tissue and emerges from the dermis below the skin surface. The needle is reintroduced in the dermis on the opposite wound.
margin and emerges from the subcutaneous tissue at the same level on the opposite side. The knot is secured and remains buried deep below the skin surface.

Scalp Laceration Repair. In contrast to small lacerations elsewhere on the body, most scalp lacerations require repair because of the propensity to bleed profusely. The dense connective tissue beneath the skin tends to hold vessels open and delay hemostasis. Frontal scalp lacerations in young men should be considered to be a cosmetically significant wound. Although the scalp laceration currently may be well hidden by hair, most men experience some balding. Care must be taken to explore the laceration thoroughly to look for a defect in the galea, an injury that requires repair with deep sutures. Staples may be ideal for the skin closure of simple linear scalp lacerations. Hair is less of a problem when placing staples, staples can be placed more quickly than traditional suture, and staples are easier to see and can be removed 1 to 3 days earlier than traditional sutures (Fig. 56-3). Staples may produce artifact on CT scan, but useful information may still be obtained if CT is necessary. Staples may move during magnetic resonance imaging and should not be placed if this imaging modality is being considered. Lightweight stapling devices are available. Most devices come preloaded with five or more staples and are easy to use.

Traditional sutures are used to repair most scalp lacerations, usually with standard nylon suture. Absorbable chromic gut can be used in children and in adults who may not return for suture removal.

Procedure. Anesthesia with epinephrine is recommended to help control bleeding. Hair removal is necessary only if the hair makes closure difficult. A defect in the galea is closed with 3-0 or 4-0 absorbable suture. Failure to repair the galea can lead to a cosmetic deformity related to frontalis muscle function. Linear superficial scalp lacerations that do not require deep sutures can be closed with staples or with monofilament nylon sutures applied using a simple interrupted or running technique. Jagged or macerated lacerations may require some débridement and horizontal mattress sutures. When one chooses to staple a scalp laceration, the adjacent skin margins are pinched together with forceps to evert wound margins. The “mouth” of the stapler is placed gently on the skin surface, taking care not to indent the skin. The handle of the stapler is squeezed carefully to eject the staple into the tissue. Ideally, the staple closely approximates the wound margins without indenting the surface of the skin. To release the staple, the wrist must be pulled back to disengage itself from the last staple.

Vigorously bleeding scalp lacerations often need temporizing measures to control bleeding while the patient is being evaluated and resuscitated. An anesthetic agent with epinephrine should be used and may be helpful to control some bleeding. Blindly clamping in an attempt to control bleeding is unwise and not likely to be successful. Raney scalp clips can be rapidly applied to the wound margins to quickly gain control of the bleeding. An applicator is used to apply and remove the clips so that they can be replaced with sutures once the patient

has been stabilized. The clips are plastic and will not interfere with CT or magnetic resonance imaging. Staple removal is simple, especially if the patient has kept the wound clean and free of dried secretions. The dual prongs on the disposable staple remover slide under the staple crossbar. As the handle is squeezed and the horizontal aspect of the staple is depressed, the sharp edges are eased out of the tissue for removal.

Vertical Mattress Sutures. Vertical mattress sutures improve wound edge eversion. They are also used for the closure of gaping wounds and deep lacerations that may need more than simple sutures to close potential dead space. Areas of lax skin tension, generally where maximal skin mobility is needed such as over joint surfaces, may need assistance to ensure eversion of the wound margins. Vertical mattress sutures may be ideal to accomplish both tasks.

Procedure. A vertical mattress suture is a combination of deep and superficial components. The needle is introduced at a 90-degree angle approximately 1 cm from the wound margin. The needle courses through the depth of the wound and emerges on the opposite side, 1 cm from the laceration margin at a 90-degree angle. The needle is reintroduced 1 or 2 mm from the epidermal edge for final approximation of the wound.

Horizontal Mattress Sutures. Horizontal mattress sutures are useful to help disperse excess skin tension and to evert wound edges. The scalp, which has minimal skin mobility, is one area where gaping lacerations may benefit from this tension-reduction method. Horizontal mattress sutures may also be beneficial in thin, fragile skin of elderly people and for lacerations that have lost tissue from the injury or débridement.

Procedure. The initial step is to pass the needle as for a simple interrupted stitch (Fig. 56-4). On exiting the skin, however, the needle is reintroduced approximately 0.5 cm adjacent to the exit point. This second “bite” re-emerges 0.5 cm adjacent to the initial insertion point and is tied. In contrast to the vertical mattress, each bite is always the same distance from the wound margin.

Dog-Ear Deformity Repair. Some redundant tissue may result on one side of the repair as the closure nears completion, especially in the closure of curvilinear lacerations. This redundant tissue generally can be avoided by placing the initial suture in the middle of a curvilinear wound. If the clinician has limited experience, excising and undermining tissue are likely to result in complications and should not be attempted.

Procedure. The laceration repair begins in a traditional manner and continues to approximately the final 1 cm of the wound (Fig. 56-5). A short incision (approximately 1 cm) is made from the end of the laceration at a 45-degree angle. The angle is cut toward the side of the redundant, bunched tissue. In most cases, the subcutaneous tissue from the start of the dog-ear defect to the newly created end of the wound must be gently undermined to mobilize the skin. The next step, the final step before suturing, is the most important. The work that has just been completed leaves a small triangular piece of excess tissue. The redundant piece is gently lifted with the tissue forceps and excised in a line parallel to the incision made above. The wound can now be closed with simple interrupted suture technique. Poor technique can result in a more unsightly repair. If too much tissue is undermined, the edge of the skin can lose its blood supply and necrose.
Corner Stitch (Half-Buried Horizontal Mattress Sutures). Jagged and triangular-shaped wounds create corners that can be difficult to repair. The clinician must avoid placing the suture directly in the tip of the flap. This practice may “stretch” the tissue and further compromise blood flow to the wound margin. The corner stitch allows optimal tissue approximation with minimal tension.

Procedure. The needle is introduced percutaneously through the nonflap side of the wound a few millimeters from the corner of the wound (Fig. 56-6). The needle is passed horizontally through the dermis of the flap. The final step is to pass the needle into the dermis of the nonflap aspect of the wound a few millimeters from the opposite side of the corner. The suture is led out through the epidermis and tied. This technique can also be used to encompass multiple flaps either individually or simultaneously if the tips are adjacent to one another. The most difficult but important aspect of the corner stitch is to take bites of equal depth with each pass of the needle. Failure to take equal bites of tissue results in a wound with opposing sides that do not lie flat; this leads to a more obvious scar. When the corner has been repaired, the remaining two sides of the wound may be closed with simple interrupted or running suture technique.

V-Y Wound Closure. The V-Y closure is indicated for the repair of V-shaped wounds with tissue loss or with nonviable margins that must be trimmed. The tissue loss is such that the adjacent mobile tissue is not sufficient to close the remaining defect.

Procedure. Nonviable tissue is trimmed with fine iris scissors (Fig. 56-7). The long V-shaped portion of the wound is sutured with simple interrupted percutaneous stitches. This first step brings the tip of the flap closer to the newly created corner of the wound. A corner stitch is used to secure the tip of the flap. The remaining limbs of the Y can be repaired with simple interrupted stitches. Some degree of undermining is likely to be needed to mobilize tissue to close the defect. Débridement of too much tissue can make the final repair more difficult and can distort adjacent anatomy.
Materials

In the Middle Ages and earlier, materials used to close wounds included flax, hemp, fascia, hair, linen strips, pigs’ bristles, reeds, grasses, and even the mouth parts of the pincher ant. In the early 1900s, natural organic protein products, including silk, cotton, and catgut, were the only available substances. Polyester (Dacron) and nylon were the first synthetic materials available in the 1940s. Since then, a host of other synthetic materials have become available.

Suture. The ideal suture is inert to metabolism, is resistant to infection, has great tensile strength, does not tear tissue, is easy to work with and tie, and is available in convenient colors with a variety of cutting and noncutting needles (Table 56-2). A common classification of suture material relies on relative absorbability. In general, the materials that maintain their tensile strength for more than 60 days after implantation have been defined as nonabsorbable. Materials that undergo rapid degradation in tissue and lose their strength in less than 60 days are considered absorbable. A second classification considers the source and nature of the material. Biologic substances, which include catgut, collagen, silk, linen, and cotton, generally produce the greatest tissue reaction and have the lowest relative tensile strength but have good knot security. These characteristics are in contrast to synthetic materials, such as polyester (Dacron), polyamide (nylon), polypropylene (Prolene), polyglycolide and polylactide polymers (Dexon and Vicryl), polydioxanone (PDS), and steel, which usually have less tissue reactivity, greater strength, and less knot security.

Knotting properties and handling characteristics tend to vary inversely. Knot security is of particular importance in maintaining wound closure and the patient’s confidence in the physician. Sutures with smooth or slippery surfaces produce little friction and glide effortlessly through tissue and are easy to tie. Smoother materials are more difficult to handle and more likely to untie spontaneously. Certain monofilament synthetic materials tend to return or spring back to their original shape. To overcome this suture memory, the first part of the tie should be a “double throw” pulled tightly enough to approximate the tissue, taking care not to strangulate the margins. The second throw locks the tension of the first part into position. A third throw is used for added security. If done properly, additional knotting is not needed after the third throw.

The presence of any suture material in a wound increases the likelihood of infection. Subcutaneous sutures bear the greatest risk. The degree of risk depends on characteristics of the substances used. Braided multifilament materials, such as the polyesters, polyamides, polyglycolides, and silk, yield the highest infection rates, whereas monofilament synthetic substances have the lowest risk of infection. There are several nonabsorbable monofilament synthetic sutures and one absorbable monofilament (PDS). The degree of infectivity of PDS compares well with the low rates of infectivity of similar materials.

Consideration of patient comfort in suture selection is important. Although silk is highly reactive, it ties well, is easy to handle, and is comfortable for the patient. It is an excellent choice in and around the lips, where comfort is a major concern. PDS is a comfortable absorbable suture and can be left in intraoral mucosa to be absorbed, with apparently low risks of infection, or it can be removed in 5 to 7 days. Staples or metallic sutures are excellent when strength is needed, but they may be uncomfortable for the patient. Nylon and polypropylene, which are the most common sutures used on skin, produce
little tissue reaction and offer good tensile strength. They tend to be stiff, produce discomfort near the lips, have poor knot security, and may be difficult to work with. A braided, coated polyester nonabsorbable material, such as Ethibond, is easier to work with and has better knot stability. Although Ethibond is more expensive than nylon, its characteristics and added patient comfort suggest that it may be preferable. Absorbable suture materials, such as polyglycolide and polylactide polymers (Dexon and Vicryl), have been used strictly for subcutaneous and mucosal closures. Their highly reactive nature allows them to be broken down and absorbed over weeks. Chromic catgut, another absorbable material, has been shown to be safe and effective for the closure of scalp wounds in children.\textsuperscript{49}

**Needles.** Surgical needles are available in a variety of sizes and shapes with a myriad of other characteristics. Cutting needles may be reverse cutting, conventional cutting, taper cut, or precision point. Most emergency wounds may be closed using a conventional cutting needle. In addition to its sharp point, it has two opposing cutting edges, with a third on the inside curve. Precision point needles are similarly shaped but are honed 24 extra times and maintain their added sharpness longer. These needles are used for delicate plastic or cosmetic surgery. Noncutting needles are reserved for organ repair and subcutaneous suturing. Cutting needles may also be used to repair subcutaneous tissue. Needle nomenclature is confusing and varies by manufacturer.

**Tape.** Tape closure may be superior to sutures and staples if applied in the appropriate circumstances. Generally, the laceration should be linear and subjected to weak static and dynamic forces. Tape is not considered for wounds requiring meticulous tissue approximation. Compared with other closure materials, application of tape is associated with lower risk of infection, less expense, and less physician time. In addition, a painful injection of local anesthetic is not needed.

The ideal wound closure tape must allow water and gas exchange and possess elasticity, strength, and optimal adhesiveness. To maximize adhesive properties, tincture of benzoin should be painted on the skin adjacent to the wound. Care must be taken to avoid introducing benzoin compound in the wound. A nonwoven, microporous tape, which is not reinforced, has been found to best meet these requirements.\textsuperscript{50,51}

**Staples.** Staples offer several advantages over sutures. Monofilament stainless-steel staples offer less risk of infection than even the least reactive suture.\textsuperscript{52} The time necessary to accomplish closure may be significantly lessened. Acceptable wounds must be linear and subjected to weak skin forces. Wounds requiring accurate approximation of tissue are not candidates for staple closure. Staples are also uncomfortable while in situ and on removal. Stapled wounds gain tensile strength sooner,

and the staples can be removed 1 to 3 days earlier than sutures. After removal, the staples should be replaced with wound closure tape for continued reinforcement.

Various stapling devices are available. The device must allow good visual access and flexible positioning for difficult angles. A precocking mechanism is necessary to allow the physician to hold the staple securely during its placement. The angle of staple delivery is important. One brand releases the staple perpendicular to the wound with its crossbar flush with the skin; this can result in cross-hatching on the skin or tissue strangulation if placed too deeply. The device needs an ejector spring for smooth staple release and must handle without producing fatigue.

**Tissue Adhesives.** European and Canadian physicians have used tissue adhesives (butyl 2-cyanoacrylates) for many years. In 1998, octyl-2-cyanoacrylates were approved for use in the United States. Tissue adhesives offer many advantages over traditional sutures. The emergency physician can apply the adhesive quickly and easily with a minimum of patient discomfort. In addition, suture removal in 7 to 10 days is unnecessary because the adhesive sloughs off the skin in approximately the same amount of time. Evidence indicates that adhesives not only provide their own dressing but also have antibacterial properties and may decrease the rate of wound infections. Considering time and materials, closing wounds with adhesives is less expensive than traditional suturing and carries no risk of needle-stick injuries.

Tissue adhesives achieved cosmetic results similar to those of traditional sutures in randomized trials. Tissue adhesive may be applied in high-tension areas, but only if used in conjunction with subcutaneous or subcuticular sutures. If used alone, tissue adhesives are not recommended for lacerations longer than 4 cm or in areas of higher tension or frequent repetitive movements, such as joints or hands.

Other disadvantages of tissue adhesives include the inability to use antibacterial or other petroleum-based products on the wound, the recommendation not to swim to limit forces that may prematurely remove the adhesive, and the greater risk of dehiscence. The tensile strength of tissue adhesives is significantly less than that of sutures. Despite these disadvan-
tages, tissue adhesives represent a tremendous advance in the management of routine uncomplicated lacerations in nontension areas. Patients routinely prefer tissue adhesives over traditional sutures.

Application of tissue adhesive begins with routine skin and wound preparation. The area must be dried and adequate hemostasis achieved before application of the adhesive. The wound margins should be approximated as meticulously as possible, and care should be taken to prevent adhesive from getting between the wound margins. Applying tape (Steri-strips) prior to application will facilitate wound margin approximation and make it easier to apply. Adhesive between the wound margins delays healing and increases the likelihood of wound dehiscence. The adhesive should be applied to the entire length of the wound sufficient to cover 5 to 10 mm of skin adjacent to the margins. Three layers of adhesive are to be applied. The physician should allow 30 to 45 seconds for the first layer to polymerize and then apply the subsequent two layers, allowing approximately 10 seconds between applications. Special care must be taken to ensure that the adhesive does not run off and disturb adjacent tissues. Lying the patient on the affected side will help avoid contamination of the eye near the wound and the opposing eye. Newer, high-viscosity formulations are now available that help limit this risk. Wounds may get wet but should not be immersed in water and should be blotted dry and not vigorously rubbed. An additional dressing may be desired by the patient but is not necessary.

Antibiotic Prophylaxis

Routine antibiotic prophylaxis for simple wounds has no scientific basis. A meta-analysis compared the rates of infection in patients with simple, nonbite wounds receiving antibiotics with those of control groups. Of 1734 patients enrolled in the seven studies, patients treated with antibiotics had a slightly greater incidence of infection. The authors concluded that prophylactic antibiotics had no role in simple, nonbite lacerations. Routine antibiotic use also has complications: Increasing resistance to antibiotics, gastrointestinal side effects, and allergic reactions are common and may result in significant morbidity and unnecessary cost.

Although irrigation and débridement are the most important means of preventing wound infections, antibiotic prophylaxis is recommended in some circumstances. Prophylaxis must be tailored to each patient. Some recommendations are supported by scientific data, whereas others have few data to support their use and are based on custom.

Contamination, Crush, and Host Factors

Antibiotic prophylaxis is often provided for patients with wounds with gross contamination, patients with severe crush injuries, and immunocompromised patients. Some authors recommend not closing these wounds and instead using delayed primary closure. If circumstances require wound closure despite the infection risk, many emergency physicians recommend prophylaxis despite scarce data.

Some authors believe that a patient with significant crush injury requires antibiotics. Crush injuries are high-risk wounds because they produce more devitalized tissue. A definitive answer may not be forthcoming because it would be difficult to complete a well-controlled prospective, blind study.

Patients with certain risk factors have increased wound infection rates. A prospective study of more than 23,000 surgical wounds showed an increased rate of wound infection in patients with diabetes, obesity, malnutrition, chronic renal failure, advanced age, and chronic steroid use. Because of higher rates of infection, some authors suggest the use of antibiotics in these patients, again based on individual circumstances. No controlled studies of antibiotic prophylaxis in these patients exist, however. Finally, some authors advocate prophylaxis for other host factors, such as prosthetic joints or risk for endocarditis. Little evidence exists to support either recommendation.

Open Fractures, Joint, and Gunshot Wounds

Wounds that involve joints or open fractures need prophylactic antibiotics. Prospective randomized controlled studies have documented decreased infection rates in patients receiving antibiotics compared with placebo. Indeed, the time to antibiotic administration in these wounds was found to be the most important factor in decreasing wound infection rates. Open fractures without evidence of significant soft tissue damage (avulsions and crushed or devitalized tissue) require antibiotics for 24 hours. Open comminuted fractures or fractures with significant tissue damage require 72 hours of antibiotics. For gunshot wounds, which are classified as a type of open fracture, the recommendations vary with the type of missile wound. Low-velocity missile wounds not treated with antibiotics showed no increased infection rate in a randomized controlled trial of 67 patients with fractures treated with a closed technique. High-velocity wounds with fracture, on the other hand, are associated with an increased risk of infection, and antibiotic therapy should be initiated early and maintained for 48 to 72 hours. In addition, shotgun wounds with fracture should have prophylaxis as well. Appropriate antibiotic therapy would be a cephalosporin with or without an aminoglycoside plus penicillin (to cover *Clostridia* species).

Bites and Puncture Wounds

Antibiotics are indicated for through-and-through intraoral lacerations, cat bites, some dog bites, some human bites, and some puncture injuries to the foot.

**Cat Bites.** Prophylaxis is required for patients with cat bites. These bites tend to be deep puncture wounds that are difficult to irrigate adequately. These wounds also tend to become infected at a much higher rate than other types of bites. Cat bites have been reported to cause infections in 10 to 40% of all wounds. In one study, 12.9% of patients had signs of infection when they presented to the emergency department, and 15.9% eventually developed infection. Other authors report that 80% of these bites become infected, although obvious selection bias limits this interpretation. Antibiotics seem to decrease the incidence of infection.

The organisms found in cat bites include *Staphylococcus* species, *Streptococcus* species, and, most often, *Pasteurella multocida*. *Pasteurella multocida* is usually found in infected cat bite wounds and is present in the normal oral flora of 70% of all cats. *Pasteurella multocida* is sensitive to penicillin, but the infection is often polymicrobial. *Pasteurella multocida* is resistant to dicloxacillin, cephalaxin, and clindamycin, and there are many erythromycin-resistant strains. Amoxicillin with clavulanate is the current recommendation for antibiotic prophylaxis for cat bites.

**Dog Bites.** Antibiotic prophylaxis for dog bites is more controversial. The infection rate has been reported as 6 to 16% for patients not receiving antibiotics. Dog bites tend to be more crush injuries with tearing and avulsions rather than puncture wounds. As such, dog bites are usually more amenable to irrigation and débridement. Seven of eight randomized trials of dog bite wounds showed no benefit with antibiotics. However,
Hand Bites. In addition to the previous bite wound recommendations, antibiotic prophylaxis of injuries to the metacarpophalangeal joints is advised. These wounds are assumed to be human bites until proved otherwise. Also known as “fight bites,” these wounds have a high incidence of infection. Patients without signs of infection may be managed as outpatients. Close inspection after anesthesia is applied is necessary to thoroughly evaluate the area for tendon involvement and/or penetration of the joint. If the joint is involved, aggressive irrigation is required. Some institutions take all these patients to the operating room for a thorough washout. Patients with early signs of infection must be admitted for intravenous antibiotics and aggressive débridement and irrigation. The choice of antibiotics reflects the predominant organisms of hand bite infections. *Streptococcus* and *Staphylococcus* species are common, but *Eikenella corrodens* and *Bacteroides* species are also typical pathogens. Because *Eikenella* is often resistant to clindamycin, first-generation cephalosporins, and erythromycin, patients with early infection should receive amoxicillin with clavulanate. Patients with later infection should receive intravenous extended-spectrum antibiotics (e.g., ampicillin with sulbactam).

_Intraoral Lacerations._ Lacerations of the oral mucosa involve bacteria-rich oral secretions and may become infected slightly more often (6–12%) than other wounds. Although few data suggest a clear indication for prophylactic antibiotics, one study showed that patients benefit from antibiotics if they are compliant with their regimen. Rates of infection for through-and-through lacerations may be twice the rates for simple lacerations. It may be reasonable to limit antibiotic use to these patients. Penicillin is an appropriate choice of antibiotic.

_Puncture Wounds of the Foot._ Puncture wounds of the foot are seen frequently in the emergency department. These wounds are often caused by common nails, although other objects (e.g., glass, metal, and wood) must be considered. Despite their simple appearance, these wounds may produce significant morbidity. The infection rate for puncture wounds has been reported to be 15%. Most wounds occur on the plantar surface, from the neck of the metatarsal to the toes. Simple cellulitis accounts for half of these infections. More significant infections include septic arthritis, abscesses, and osteomyelitis. *Pseudomonas* organisms cause 90% of osteomyelitis cases from puncture wounds. No data suggest a benefit from prophylactic antibiotics, but given the high risk of infection and serious complications, their use should be strongly considered in select puncture wounds. Consideration of *Pseudomonas* organisms when the puncture went through a rubber-soled shoe is essential. Patients with puncture wounds to the foot require early follow-up. Ciprofloxacin is the drug of choice to treat outpatients with suspected wound infection when *Pseudomonas* is of concern. Cephalexin (kefllex) or dicloxacillin is adequate for staph and strep coverage unless methicillin-resistant *Staphylococcus aureus* (MRSA) is likely. In cases suspicious for MRSA, sulfa/trimethoprim or doxycycline is recommended.

_Drains, Dressings, and Immobilization_ Drains

Drains probably have no role in emergency department wound care. In general, drains are placed when a collection of fluid exists or may develop. The presence of a drain reduces the wound’s resistance to infection, regardless of the materials used in its construction, and the use of drains should be avoided. In wounds likely to collect fluid (e.g., around the elbow or knee), it is preferable to place the extremity at rest with a plaster splint or perform delayed primary closure.

_Dressings_ Various dressing materials are available. The microenvironment created by a dressing affects the biology of healing. The optimal wound climate must not interfere with the activity of fibroblasts and macrophages. The production of granulation tissue and migration of epithelial cells across the wound must be optimized.

Several factors should be considered when choosing the appropriate dressing. Dressings that prevent evaporation of water and keep tissues moist are helpful. A drying wound produces a thick, hardened scab that impedes the process of epithelialization. Excess fluid can lead to maceration of tissue and may be a potential culture medium for bacterial proliferation. Gaseous permeability is essential because epithelialization is accelerated greatly in the presence of oxygen. The wound-covering product should be impermeable to bacteria and other particulate matter that can contaminate the wound. It is important not to traumatize newly established tissue during dressing changes. The optimal dressing should have a nonadherent surface, be permeable to gases, and have a capacity to absorb some fluid but not allow desiccation. The outer barrier of the product should be impermeable to bacteria but permeable to water vapor. These products include films, hydrocolloids, foams, and hydrogels. The choice of dressing for emergency department wounds is primarily based on the amount of drainage that is expected.

Film dressings are thin membranes that are transparent, adhesive, and waterproof but are not absorptive. They are best reserved for wounds with low levels of drainage. Film dressings may be left in place for up to 7 days as long as they do not leak or separate from the wound bed. For wounds with a moderate amount of drainage, moderately absorptive hydrocolloid dressings may be indicated. These dressings are thicker than films, semiocclusive, waterproof, and very comfortable for the patient. Like films, they can be left on for up to 7 days. Foam dressings are more absorptive and made of a soft cushion sponge-like material. Some may require a secondary dressing for adhesion and need to be removed every 3 days. Hydrogel dressings are moisture-donating water-based gels that are available in sheets attached to a semipermeable film. These dressings do not absorb fluids, so they must be used on relatively dry wounds. Patients often find these dressings to be the most comfortable, but they need to be changed every 1 to 3 days. The least expensive and simplest method of dressing a straightforward, uncomplicated laceration is to use a Vaseline-impregnated gauze or gauze on top of a thick layer of antibiotic ointment. These should be changed daily to prevent desiccation.

_Immobilization_ Wounds in proximity to joints must be immobilized as part of routine care. Splinting the injured body part places the injury at rest and hastens healing. Failure to splint appropriately exposes the healing tissue to the dynamic forces of muscular contractions, ultimately slowing the healing process and increasing scar size. In addition, immobilization decreases lymphatic flow and minimizes spread of microflora from the wound.
Wound Care Instructions

It is difficult for patients to identify and recognize the signs of infection (Box 56-2). Discharge instructions must be clear, understandable, and reasonably comprehensive. Instructions should include daily care, observation for signs of infection, suture removal dates, and a follow-up source. During the first 24 to 48 post-traumatic hours, the injured extremity should be elevated. Elevation lessens edema, hastens healing, and mollifies pain. The wound should be protected as described previously or should be cleaned daily to remove crust formations. It is safe to bathe and get the wound wet 24 hours after injury. Daily swabbing with half-strength hydrogen peroxide rids the wound of debris and any blood clot that forms between the sutured edges. Hydrogen peroxide should not be used after separation of the scab because it is toxic to the epithelium and may produce bullae.

Wound infection is difficult for the untrained observer to distinguish from the inflammatory response of injury and subsequent healing. Patient education in this regard should be cautious and straightforward (e.g., return or follow-up for redness, swelling, increased pain, fever, pus, or red lines progressing up an extremity). An injury classified as high risk must be reexamined 48 hours after the trauma, regardless of its appearance.

Suture removal times vary, but generally they are approximately 4 days for the face and 7 to 14 days for other body parts (see Box 56-2). Considerations include cosmetics, dynamic forces in proximity to the injury, static skin tension, blood supply, and anticipated healing rates.

Tetanus Immunization

The reported incidence of tetanus in the United States in 2005 was 0.011 per 100,000 population (27 cases reported). Most tetanus patients are older than age 50 years. Immunization status needs to be considered in all patients with wounds, regardless of severity. Forty percent of all cases of tetanus occur in individuals who have either minor wounds or no collection of injury. These numbers raise serious questions regarding the validity of separating immunization recommendations according to clean and tetanus-prone wounds. Studies show that many people are inadequately immunized, especially patients older than age 70 years, immigrants, and people with no education beyond grade school. Also, patient immunization histories are often unreliable. Given the inability to predict which wounds are high risk, all wounds should be approached with suspicion.

The usual incubation period for tetanus is 7 to 21 days (range, 3–56 days). Immunization should be given as soon as possible but can be given days or weeks after the injury. The dose of tetanus toxoid (T) or diphtheria, pertussis, and tetanus toxoids (dTap) is 0.5 mL intramuscularly, regardless of the patient’s age. Inadequately immunized patients need a dose of dTap and tetanus immune globulin (TIG). The TIG dose is 250 U in patients 10 years old or older, 125 U in children 5 to 10 years old, and 75 U in children younger than 5 years old (Table 56-3). A single injection of TIG provides protective levels of passive antibodies for at least 4 weeks. The immune globulin and toxoid may be given during the same visit but should be administered with a different syringe at separate sites. Emergency physicians need to be more diligent because data suggest that TIG is rarely administered even when indicated.

Because studies suggest that 10 to 40% of the U.S. population is inadequately immunized against diphtheria, diphtheria vaccination should be given along with tetanus toxoid. Immunity to pertussis wanes approximately 5 to 10 years after vaccination. Since the 1980s, the number of reported pertussis cases has steadily increased, especially among adolescents and adults. In 2005, a total of 25,616 cases of pertussis were reported in the United States. In 2005, a tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine, adsorbed (Tdap) product formulated for use in adults and adolescents was licensed in the United States for people age 11 to 64 years. When possible, it is recommended that this triple combined formulation be used in the emergency department. Although all four injections (T, dt, TIG, and dTap) are considered safe and effective in pregnancy, because of limited experience during pregnancy the recommendation is to use dt. However, dTap is recommended immediately postpartum, including for breast-feeding women.

SUMMARY

Box 56-3 summarizes the principles of wound care management.

*Consider more frequent immunization for elderly patients. dTap recommended for ages 11–64 years (dt to be used in those older than 64 years).
†Refer these patients to complete their series; dTap in 6 weeks and 12 months. dTap, diphtheria, pertussis, tetanus toxoids; TIG, tetanus immune globulin. All injections are intramuscular.

BOX 56-3 SUMMARY OF WOUND CARE

A. Stabilize patient
B. History (include tetanus immunization and allergies)
C. Physical examination
   1. Neurovascular examination
   2. Anesthesia: bupivacaine 0.5% without epinephrine, regional or local
   3. Bloodless field: tourniquet or sphygmomanometer for extremities
   4. Sterile examination of anatomic structures, skin, nerves, tendons, blood vessels, bones, muscles, fascia, other (ducts, cartilage)
   5. Consult if indicated
D. X-ray films to detect injury to bone or the presence of foreign bodies (xeroradiograph or ultrasound)
E. Wound preparation
   1. Cut—do not shave—surrounding hair
   2. Prepare surrounding skin with povidone-iodine (Betadine) solution
   3. Sharp débridement of foreign matter and devitalized tissue
   4. High-pressure irrigation with saline, 1% Betadine, an antibiotic solution, or a nonionic solution
F. Wound closure
   1. Tape, staples, or suture
   2. Do not use subcutaneous sutures unless the wound is under high tension
G. Antibiotics
   1. Apply topical antibiotics
   2. No systemic antibiotics unless wound is very high risk
H. Dress and immobilize: Consider a transparent gas-permeable dressing
I. Wound care instructions (see Box 56-2)
   1. Signs of infection
   2. Elevation
   3. Wound check if necessary
   4. Suture removal as soon as possible

KEY CONCEPTS

- Risk factors for wound infection include prolonged time since injury; crush mechanism; deep penetrating wounds; high-velocity missiles; and contamination with saliva, feces, soil, or other foreign matter.
- The most effective intervention to decrease infection is thorough cleansing, using saline irrigation at approximately 8 psi. Attaching an 18-gauge needle to a 35-mL syringe creates an irrigant force of 7 or 8 psi, which decreases bacterial counts.
- Soaking wounds in povidone-iodine (Betadine) is more toxic than beneficial to healthy tissue.
- Antibiotics are indicated for through-and-through intraoral lacerations, cat bites, some dog bites, some human bites, puncture injuries to the foot, open fractures, and wounds involving exposed tendons or joints.
- High-risk wounds should not be sutured primarily but may be repaired in 4 or 5 days (i.e., delayed primary closure).
- Tetanus immunization should be given soon after injury but can be given days or weeks later. The usual incubation period for tetanus is 7 to 21 days (range, 3–56 days).

Chapter 57  Foreign Bodies

Stephen H. Thomas and Benjamin A. White

■ PERSPECTIVE

History

When people ingest or insert foreign bodies, a brief history may be sufficient to guide management and predict the process required for definitive resolution. The technical intervention required for foreign body removal may be more complex, sometimes requiring substantial expertise. Cases involving persistent cough after ingestion of peanuts in a toddler or abdominal pain and a history of ingesting foreign objects in a psychiatric patient should be diagnosed rapidly and easily. Sometimes, however, diagnosis and management of a foreign body may require a meticulous history and insightful care. Persons at higher risk of having a foreign body include neurologically impaired patients, edentulous persons, patients with certain psychiatric diagnoses, incarcerated persons, and patients at the extremes of age. In these same groups, definitive history often is elusive. Sometimes the clinician must use situational clues: A toddler left alone with an infant may have inserted a foreign body, or a prisoner with abdominal cramps may have ingested a foreign body for secondary gain. Even when patients are fully cooperative, the diagnosis of foreign body ingestion or insertion can be difficult. The presentation may be for a seemingly unrelated problem, and sequelae of foreign bodies may be delayed by months, years, or even decades.1

■ PHYSICAL EXAMINATION

Depending on the location of the foreign body, the physical examination can provide direct or indirect evidence of foreign bodies or their complications. Specifics are presented for each category of foreign body described later in the section on management, but with a recurring theme: Meticulous examination frequently aids in providing a diagnosis.

■ DIAGNOSTIC IMAGING

Plain radiography, classically the primary technique used for foreign body detection, often is the test of first choice. In appropriate circumstances, plain films can aid in determination of the location, size, and number of foreign objects. Even when objects are not visualized, radiographs may show secondary changes (e.g., pulmonary air trapping) providing clues to foreign body presence. To assist in the localization, two views—anteroposterior and lateral—usually are necessary. Objects such as metal or gravel, which are denser than the tissue in which they are embedded, usually are easy to visualize on plain radiographs. Organic material, may have a density similar to that of human tissue, may not be seen on plain films.

■ PRINCIPLES OF DISEASE

When the foreign body is localized, it usually is removed, either in the emergency department (ED) or in specialized areas such as interventional radiology, endoscopy, or operating suites. Although foreign body removal is not always feasible or desirable, extraction is indicated in most cases. Removal frequently is vexing for both physician and patient, so an initial discussion outlining the need for the procedure is recommended.

When the foreign body represents an immediate threat to the patient, as is the case with an airway foreign body, the need for urgent extraction is obvious. Trauma-related foreign bodies, such as knives and bullets, pose important management issues (see other chapters on trauma). Even in cases in which no immediate life threat exists, some foreign bodies should be removed because of the threat of injury from their nature or constituents. For instance, cocaine can kill a body packer,2 an impacted button battery can cause fatal electrochemically induced tissue damage,3 and an insect can damage otic structures.4

In the absence of immediate life threat or constituent-related foreign body danger, additional complications can occur. In cases involving luminal obstruction, the foreign body may become lodged and may exert pressure on adjacent tissue, with the potential for necrosis and perforation. The object also may serve as a nidus for infection that is recurrent or refractory to treatment until removal of the foreign body is accomplished. In such cases, the patient often seeks medical attention for secondary symptoms. Specific recommendations for foreign body removal are presented in the following section.

■ FOREIGN BODY MANAGEMENT BY SPECIFIC ANATOMIC LOCATION

Eye

Clinical Features. Although wooden and metallic fragments are found most frequently, ophthalmic foreign objects vary widely, from dust particles to lost contact lenses to missiles associated with penetrating trauma.5 The diagnosis usually is self-evident. With both extraocular and intraocular foreign bodies, however,
Figure 57-1. Computed tomography scan shows a right intraocular foreign body (a BB pellet) in an intoxicated patient without a known history of trauma.

the clinical presentation may be subtle, with mild symptoms and uncharacteristic history involving seemingly trivial trauma, such as brushing against a bush or falling. In some cases, foreign bodies are identified in intoxicated patients who present with abnormalities on ocular examination and no known history of trauma (Fig. 57-1). ED presentation can be delayed by days or even years after the initial incident. Early diagnosis and appropriate care and follow-up minimize the risks of delayed sequela, such as endophthalmitis (which may develop within 48 hours after foreign body introduction) or sight-threatening siderosis bulbi. The foreign body removal (and its timing) does not diminish the importance of making the initial diagnosis.

History. Most patients complain of “something in the eye” (often on blinking) and cannot see the foreign body either when looking in a mirror or on scanning the visual field. If the object is corneal, however, it may be seen by the patient from within or from without. The patient also may complain of tearing and conjunctival reddening. Foreign bodies that create corneal injury and are no longer present may account for symptoms identical to those noted in the presence of a foreign body. Additionally, patients may present with symptoms in the absence of any history of known foreign body. In these cases, the occupational and social history, including pets and hobbies, may shed light on the diagnosis. Another important component of the history is whether radial keratotomy has been performed. This procedure is associated with potential for foreign body entrapment in the corneal incisions, which can gape as long as 6 or more years after the procedure.7

Physical Examination. The initial survey should include standard elements of ED eye examination. Early visual acuity is an important predictor of final visual outcome in cases of intraocular foreign body.10 Slit-lamp examination may reveal a corneal foreign body by means of the shadow it casts on the iris. This examination also can facilitate identification of rust rings, and application of fluorescein can aid in detecting abraded corneal epithelium. The inner aspects of both lids must be examined. The upper lid should be everted by instructing the patient to look downward while upward traction on the eyelashes is applied; an applicator stick is placed on the proximal edge of the tarsal plate, to act as a fulcrum. After localization and removal of a foreign body, complete examination should seek presence of other ocular objects.

Diagnostic Strategies. The foreign body may have penetrated the anterior eye structures and entered the globe (see Fig. 57-1). If the history and mechanism of injury are compatible with ocular penetration by radiopaque material, or if a small wound of the globe is noted, obtaining anteroposterior and lateral radiographic views of the orbit is a reasonable initial step.13 However, the multiple advantages of computed tomography (CT) render this latter technique the modality of choice when intraocular penetration is strongly suspected. Compared with plain radiography, CT delivers less radiation to the lens. Multiplanar reconstruction minimizes streak artifacts, affording better localization of intraorbital objects. When globe penetration is strongly suspected, staining with fluorescein is best avoided owing to its obscuration of anatomic features on the physical exam. In cases in which perforation is judged unlikely and fluorescein is administered, identification of rivulets of fluorescein tracking from the punctum (i.e., positive result on a Seidel test) is helpful in identifying the fact that intraocular penetration has occurred.

Ultrasound imaging is a useful adjunct to CT scanning in patients with foreign bodies that are difficult to localize.13 When CT will be delayed, or if ionizing radiation is a concern, two ultrasound techniques can be useful in searching for foreign bodies. Standard B-scan ultrasonography has been shown to detect foreign bodies missed on ophthalmologic examination, as well as objects that are not seen or incompletely characterized on other imaging studies. The more advanced technique of ultrasound biomicroscopy, more likely to be available in ophthalmologic specialty centers than in general EDs, also has been shown to be helpful in foreign body imaging. The sensitivity of this modality is sufficient to detect foreign bodies not visible by direct or indirect ophthalmologic examination, traditional B-scan ultrasonography, or CT.11 In light of the lack of reported case series and justifiable concerns about eye damage from mobilization of ferromagnetic foreign objects, use of magnetic resonance imaging (MRI) for ophthalmologic foreign body imaging remains controversial.7

In some cases, orbital trauma is associated with central nervous system injury. When the workup indicates potential for injury or foreign body involving the brain, imaging of the intracranial compartment should be performed.15

Management. In nearly all cases, appropriate therapy consists of removal of the foreign body. If the object is located on the bulbar or palpebral conjunctiva (not the cornea), it often can be removed easily by sweeping the site with a moist cotton-tipped applicator. Usually, other instruments are required (Fig. 57-2). Occasionally, if the foreign body is large, it may be extracted with forceps. For small corneal foreign bodies, after application of a topical anesthetic, it is often necessary to use an eye spud or small-gauge needle, inserted gently underneath one end of the object, to pick it out; magnification usually is helpful. If this is unsuccessful or if the foreign body is deeply embedded, the patient should be referred for object removal by an ophthalmologist within 24 to 48 hours. This is particularly true with metallic foreign bodies, early removal of which decreases the size of the rust ring. Overly vigorous attempts at removal may lead to anterior chamber perforation. Avoidance of significant corneal procedures is prudent in patients who have had a laser-assisted in situ keratomileusis (LASIK) procedure to correct nearsightedness.
Figure 57-2. Instruments for removal of an ocular foreign object. Top to bottom: Forceps, needle (straight or bent) mounted on a syringe “handle,” angled eye spud, and rotating straight-tip eye spud.

After the removal of a corneal foreign body that leaves no rust ring, treatment is essentially the same as for corneal abrasion. In cases in which foreign bodies may have elicited an allergic response, topical steroids have been used. Therapy for patients with a rust ring is controversial. ED management should be dictated either by standing protocol (designed in collaboration with ophthalmologists) or by in-hospital ophthalmologic consultation. Otherwise, it is prudent to recommend evaluation within 24 to 48 hours by an ophthalmologist to consider removal of retained rust.

Ear

Clinical Features. Foreign bodies of the ear are more likely to prove problematic for ED management than foreign bodies in other locations. The difficulty has little to do with diagnosis. Rather, the problem is the need to remove objects from a sensitive anatomic area in an often uncooperative patient population. In terms of specific objects found in ears, different series list varying culprits, but common findings include insects, beans, plastic toys, and small spherical objects such as pearls, pebbles, or beads. Patients usually state that something is in the ear. If the foreign body is an insect, the patient may feel motion or hear buzzing, although less specific complaints may include itching, discharge, or otalgia. Similar secondary symptoms may be reported when noninsect foreign bodies are lodged in the ear canal. This type of presentation is especially common in children, who may fear telling of foreign object insertion into the ear; the problem is ignored until secondary problems prompt a visit to the ED.

In patients with ear complaints and travel or camping history or poor living conditions, geographic information may suggest insects inhabiting the external ear canal. Infestation with Korean or Middle Eastern mites, Malaysian ticks, and Omani beetles has been associated with various degrees of morbidity in patients spending time in those regions. In most U.S. cases, the cockroach is the culprit.

Patients with foreign bodies in the ear may present with secondary symptoms related to pathologic changes in adjacent structures. Malocclusion may be the chief complaint if the foreign body erodes to the temporomandibular joint. Similar erosion has caused otic foreign bodies to manifest as eustachian tube dysfunction, parapharyngeal abscess, or mastoiditis with progression to fatal brain abscess and meningitis. Such events are rare.

It is important to ask patients about previous attempts at foreign body removal, because these efforts may have caused further problems. Poorly executed attempts at foreign body removal may injure the ear canal, perforate the tympanic membrane, or merely push the foreign body deeper into the canal. Irrigation may cause enlargement of the foreign object, especially if it is vegetable matter.

Physical Examination. The external auditory canal is cylindrical with an elliptical cross section (Fig. 57-3). A thin layer of sensitive epithelium covers an outermost cartilaginous portion and an inner bony segment. Two anatomic points of narrowing (and foreign object lodging) are present within the canal: (1) near the inner end of the cartilaginous portion of the canal and (2) at the point of bony narrowing called the isthmus.

The first factor crucial to successful examination is adequate lighting that can be directed by the operator. This may be a strong light source and a head mirror, a headlamp, an operating otoscope, or an operating microscope. A large-size speculum is essential to obtain an adequate field of view and to enable four-quadrant injection of local ear canal anesthesia when necessary for foreign body removal. As with any examination involving the external auditory canal, the pinna of the ear is grasped and then retracted in a posterosuperior direction to straighten the canal and afford a more complete view.

Inspection of the tympanic membrane is important because it may have been ruptured by the foreign object or by previous removal attempts. If so, medical documentation should indicate that this injury was present before attempts at foreign object removal. As in other body locations (especially the nose), the risk of multiple foreign objects is such that if one foreign object is identified, a search for additional material is warranted.

Diagnostic Strategies. Diagnostic imaging rarely plays a role in the ED workup of suspected otic foreign bodies. The primary indication is to identify complications from foreign body presence. CT or MRI may be performed to characterize infectious or erosive sequelae of ear canal foreign objects.

Management. In most cases, foreign body removal attempts may be instituted in the ED. Neither presence of the foreign
body for more than a day nor very young patient age (younger than 4 years) constitutes an independent risk factor for foreign body removal failure or complications; the emergency physician may thus proceed with removal efforts if not otherwise contraindicated.\textsuperscript{26} The patient should be informed about the extreme sensitivity of the auditory passage and the likely discomfort and potential for minor bleeding. Sedation may be important to minimize patient discomfort and reduce risks of iatrogenic trauma. Lidocaine instillation may aid in topical anaesthesia; liquid 1 or 2\% solution is preferred to gel preparations, which impair visualization. Less often, foreign body removal requires local anaesthesia of the external ear canal. The anesthesia instillation procedure, which may cause patient discomfort and iatrogenic injury, is performed by injecting all four quadrants of the canal with lidocaine using a tuberculin syringe inserted through an otic speculum. In cases of a refractory foreign body and an uncooperative patient, definitive management should be performed with procedural sedation or even general anaesthesia. Although the evidence is not universally consistent, available data suggest that approximately 95\% of aural foreign bodies can be removed without the need for general anaesthesia.\textsuperscript{17,26}

When the ear canal is inhabited by an insect, it is important to kill or immobilize the creature to facilitate its removal. Such precautions reduce the chance of patient discomfort or ear damage caused by an insect attempting to evade forceps introduced into the ear canal. Different immobilizing agents have different reported success rates. Efficacious formulations include lidocaine as a 10\% spray or less concentrated liquid, 2\% lidocaine gel, mineral oil with 2\% or 4\% lidocaine, and alcohol.\textsuperscript{3}

Any of several extrication methods may prove effective, and various instruments may be useful (Fig. 57-4). Small objects can often be removed by the application of suction with a small plastic catheter. With soft or irregularly shaped objects, it often is possible to grasp the foreign body with forceps (alligator forceps may be best) and remove it either in one piece or in fragments. If the object cannot be grasped, removal may be possible by passing a blunt-tipped right-angle hook beyond the foreign body and then gently coaxing it out. Alternatively, a balloon-tipped catheter can be passed distal to the object, with subsequent attempts to withdraw the (inflated) balloon and extract the object. Any balloon-tipped catheter design may be used, so long as its caliber is small enough (approximately 18 gauge or less) to allow comfortable introduction into the ear canal; a typical commercial device is shown in Figure 57-5.

Indirect methods for foreign body removal also have been used with some success. The irrigation technique takes advantage of the elliptical shape of the external ear canal. A stream of room-temperature water or saline should be directed at the (nonvegetable) foreign body periphery, using a 20 mL syringe and a 14- or 16-gauge catheter (this setup is safe in terms of pressure on the tympanic membrane).\textsuperscript{27} The hope with irrigation is that the jet of water will be directed past the object, against the tympanic membrane, and finally against the posterior aspect of the foreign body, driving it out of the canal. In a study examining the use of an electric ear syringe for removal of foreign bodies from the ear canal, the syringe outperformed the other techniques used for comparison.\textsuperscript{28} No significant complications were reported with use of this technique, and it was well tolerated by children and adults. This modality should not be used in patients with a known history of or clinically suspected tympanic membrane perforation.

Removal of objects from the middle ear with cyanoacrylate adhesive–tipped swabs has been recommended in the past. This technique carries the risk, however, of contaminating the ear canal with a substance that is difficult to remove and has been associated with tympanic membrane rupture.\textsuperscript{29,30} Insufficient evidence exists to condone or condemn this technique.

If these methods are unsuccessful or if the patient, especially a child, is uncooperative or in undue distress even with procedural sedation, removal efforts should cease and the patient should be referred to an otolaryngologist. In most cases, the patient should be discharged directly to the otolaryngologist’s office. If the clinical scenario (e.g., acceptable patient comfort level, low-risk foreign body) seems to be amenable to nonemergent follow-up, arrangements should be made for the patient to see the otolaryngologist in a day or two. Rates of operative intervention vary in published series. Studies’ case mix differences probably are responsible for the varying rates (from 5 to 33\%) of reported need for surgical removal of otic foreign bodies.\textsuperscript{17,20,26}

Inappropriately prolonged efforts at foreign object removal can result in wasted time, unnecessary patient discomfort, and high potential for complications as previously noted. Patient apprehension, distal foreign body movement, or damage to the ear canal (including induction of edema) may prompt surgical intervention that would have been otherwise unnecessary.\textsuperscript{16,31}

\textbf{Figure 57-4.} Instruments that may be useful for removal of a foreign body from ear canal or nares. \textit{Clockwise from left:} Right-angle probe, suction catheter, alligator forceps, nasal speculum, and bayonet forceps.

\textbf{Figure 57-5.} Balloon-tipped catheter, which can be used for removal of otic or nasal foreign bodies.
Otic foreign bodies are associated with many sequelae, but these usually are not serious. The most commonly occurring complications in pediatric series are external ear canal bleeding (approximately 16%), otitis externa (6%), and tympanic membrane perforation (2%).\(^\text{37}\) One large series suggests that, perhaps as a result of relative delay in seeking medical attention, otitis externa is significantly more likely in adults than in children.\(^\text{32}\)

After removal of the foreign body, canal examination should be repeated to ensure the absence of retained material and to evaluate otic anatomy. In cases in which the tympanic membrane is ruptured and the middle ear is at risk for infection, appropriate oral antibiotics are recommended. Topical antimicrobial therapy decreases the risk of external otitis; one method packs the meatus with ribbon gauze impregnated with a broad-spectrum antibiotic.\(^\text{4}\) Follow-up evaluation should occur within 2 to 3 days for cases involving tympanic membrane rupture, or in those for which foreign body removal was traumatic (to assess for external otitis).

**Nose**

**Clinical Features.** The nose is perhaps the most common site for the insertion of foreign bodies by children.\(^\text{33}\) Among the nasal objects found most frequently are beans, sponge pieces, pebbles, plastic toy fragments, and other small round objects.\(^\text{34}\) Perhaps because most people are right-handed, most nasal foreign bodies are right-sided.\(^\text{25,35}\) Compared with patients with ear canal foreign bodies, children with nasal foreign bodies tend to be younger (most commonly younger than 5 years of age).\(^\text{24,25}\)

Nasal foreign bodies are less problematic than foreign bodies in other locations. ED removal is nearly always successful, and with proper technique (e.g., care to avoid aspiration), serious sequelae are rare.\(^\text{35}\) The infrequently encountered cases involving intranasal insertion of an alkaline button battery, which may cause electrical or chemical burns with liquefaction necrosis or may be accidentally aspirated during attempts at removal, constitute an exception to this rule.\(^\text{24,34,36,37}\)

**History.** Although most patients seek medical attention within 24 hours, patients with nasal (versus otic) foreign bodies are more likely to present with secondary symptoms and delays of 1 week.\(^\text{36}\) In fact, nasal foreign bodies may be asymptomatic, identified as incidental findings on imaging studies obtained for other purposes.

Patients seen in the ED with a nasal foreign body usually have one of two histories. With the first type of presentation, the patient admits to, or is seen, placing an intranasal object. This is the most common history. Other patients present with a constellation of signs and symptoms: purulent, unilateral, malodorous nasal discharge or even persistent epistaxis. These patients often are misdiagnosed and treated with antibiotics for supposed sinusitis. Unresolving sinusitis despite appropriate antibiotic therapy should alert the emergency physician to the possibility of nasal foreign body.\(^\text{38}\)

Foreign objects placed intranasally may purposefully or inadvertently end up in the sinuses. These foreign bodies require more invasive intervention, and psychiatric evaluation of the patient may be indicated when self-injury is suspected. When the history suggests a foreign body but none is identified on nares examination, imaging the sinuses should be considered.

**Physical Examination.** As with foreign bodies of the ear canal, it is important to prepare the patient (and the parents) for examination and subsequent removal attempts. Because of risks of iatrogenic movement of the foreign body further posteriorly or into the airway, children may need to be restrained to permit the examination. Physical examination sometimes can be delayed until after insufflation of the nares is attempted. The nasal mucosa normally is quite sensitive, and this sensitivity is increased by any infection or irritation. Examination is facilitated by provision of topical anesthesia and vasoconstriction to the nasal mucosa. Examination should include both nares, with adequate lighting and visualization using a nasal speculum. The presence of the foreign body and any secondary tissue damage should be noted. Necrosis of the nasal mucosa and septum may accompany button battery impaction.\(^\text{37}\)

During the examination, care is taken not to dislodge or drive the foreign body posteriorly into the nasopharynx and risk aspiration. In some circumstances, it may be prudent to place patients in lateral decubitus, perhaps with additional Tendelenburg positioning, to help prevent aspiration of objects that are pushed into the posterior pharynx.

**Diagnostic Strategies.** Diagnostic imaging does not play a major role. When intrasinus foreign bodies are suspected, CT can be helpful. Rarely, CT or MRI may be indicated to visualize suspected foreign bodies or their complications.

**Management.** In most cases, removal of a nasal foreign body is readily and safely accomplished in the ED. Although the avoidance of iatrogenic injury is paramount, the structures local to an intranasal foreign body are not as sensitive or easily damaged as structures in other body cavities (e.g., the ear canal) that may harbor foreign objects. Accordingly, the need for subspecialty consultation and operating room removal is rare.\(^\text{24,25,34}\)

Occasionally, positive pressure applied to the patient’s mouth achieves rapid foreign body dislodgment while obviating the need for restraint, sedation, and other requirements attendant to more invasive removal techniques. This technique is a quick and safe primary intervention. The underlying principle is that a short burst of air blown into the mouth of a child, with finger occlusion of the nonobstructed naris, may force the foreign object out of the nose. Pretreatment with vasoconstrictive spray may improve the chances of success.\(^\text{38}\) The insufflation, preferably applied as a “kiss” from a parent, also can be provided by a manual ventilation bag. The insufflation technique is quite useful, particularly in preschoolers, who are likely to be uncooperative with other removal modalities. Many children can be instructed to take a deep breath and blow hard through the nose as a parent closes the unaffected naris. An otherwise troublesome removal often can be accomplished quickly and easily by this method.\(^\text{35,38,39}\)

When positive-pressure insufflation is not warranted or is unsuccessful, use of instruments and specialized removal techniques may be required (see Figs. 57-4 and 57-5).\(^\text{34}\) Regardless of the method, the patient (usually a child) may benefit from some combination of restraint, sedation, and pretreatment with vasoconstrictive (e.g., nebulized racemic epinephrine) and anesthetic (e.g., benzocaine spray) agents.\(^\text{38}\) Adequate illumination is essential. Necessary instruments include a blunt-tipped right-angle probe, suction catheter, and alligator forceps. The forceps is used when the foreign body is to be directly grasped, and the right-angle probe is used in an attempt to reach proximal to the foreign object and displace it forward. Other useful instruments include Fogarty (vascular) and Foley catheters; “specialized” balloon-tipped catheters also are available in many EDs (see Fig. 57-5).\(^\text{35,34}\) Suction is necessary primarily for removing purulent secretions and any blood that may obscure the field. In some cases, suction can be used to withdraw foreign bodies directly. Suction may be useful with hard-to-grasp objects or small soft objects not tightly lodged in place. The use of cyanoacrylate-tipped swabs may be useful in certain circumstances. As noted previously with respect to
otic foreign bodies, the available evidence is insufficient to permit definitive conclusions about this approach.

Airway

Clinical Features. Although improved diagnostic and therapeutic techniques have markedly reduced fatality rates from foreign body inhalation, airway tract foreign objects still cause a significant number of deaths and cases of anoxic brain damage annually. In a large-city series of ambulance-transported patients with an airway foreign body, a 3.3% mortality rate (an average of one patient per month) even before arrival at the ED was reported.\(^4^0\)

Alternatively, airway foreign objects can manifest less dramatically than acute respiratory distress and can go undiagnosed for years. Delayed diagnosis is common. Only one half of the patients in a pediatric series of lower respiratory tract foreign body presented within 1 day of aspiration; an additional 20% presented during the first week, and another 20% presented after a delay of more than 1 week.\(^4^1\) Patients with uncharacteristic presentations may have unusual foreign body introduction mechanisms, such as ingestion or penetrating trauma.\(^1\) Patients with altered mental status from a variety of causative disorders are at risk for occult aspiration, which may be difficult to diagnose.

The most common airway foreign bodies in one series were ingestible agents, primarily meats and medications.\(^4^0\) Airway foreign body series also identify pins, needles, jewelry, and ingestible agents, primarily meats and medications. Airway obstruction at the laryngeal or subglottic level. Foreign bodies that pass beyond the trachea are less likely to cause acute hypoxic crisis but can lead to substantial respiratory embarrassment and can be difficult to remove. In adults, bronchial foreign bodies are found more often in the right bronchial tree. In one large series, 69% of bronchial foreign bodies were right-sided.\(^4^5\) Because the main bronchi branch from the trachea at more equal angles in children, occurrence rates for the left-right distribution of lower airway foreign bodies are approximately equal.\(^4^1\) Foreign objects can be bilateral, with 3.6% of patients in one series found to have foreign bodies in right and left main bronchi.\(^4^5\)

History. Clinical presentation can range from chronic nonspecific respiratory complaints to acute airway obstruction.\(^5^0\) In most aspiration cases, foreign body presence is suspected after a thorough history. The most dramatic cases typically involve a history of what is commonly termed the “café coronary”: The patient attempts to swallow a food (usually meat) bolus larger than the esophagus can accept. The bolus lodges in the hypopharynx or trachea. Often there is confusion over whether the patient is having a myocardial infarction or has an obstructing foreign body, but the conscious cardiac patient is able to speak. Patients with airway foreign bodies may exhibit noisy breathing, inspiratory stridor, vomiting, and possibly slight hemoptysis.\(^4^0\)

Some patients may give a history similar to that in café coronary, with resolution of major symptoms. These symptoms—a choking sensation accompanied by respiratory distress with coughing, wheezing, and dyspnea—occur in up to one half of patients who aspirate and are collectively known as the penetration syndrome (object penetrates airspace).\(^5^0\) Symptom resolution may result from spontaneous clearance of the foreign body by coughing. In some cases, coughing does not eject the foreign body completely but rather results in its impaction in the subglottic region.\(^4^7\) A retained airway foreign object should be considered in cases in which the patient history is one of perceived foreign body followed by cough with incomplete (or even complete) post-tussive symptom resolution.

In a 20-year series of adult and pediatric patients with suspected foreign body aspiration, sudden onset of choking and intractable cough were present in one half of the cases, with eventual foreign body identification.\(^5^5\) In addition to coughing and choking, stridor is a frequent component of an acute aspiration episode in patients of all ages.\(^5^7\) Symptom distribution is similar in adult and in pediatric patients,\(^4^5\) but choking and wheezing appear more prominently in the pediatric literature. In a series of 87 pediatric patients with suspected foreign body, 96% had a history of a choking crisis.\(^5^3\) Wheezing is common, having been reported in up to 75% of patients from 8 to 66 months of age with airway foreign bodies.\(^4^6\)

Most patients who have aspirated objects have persistent symptoms (e.g., cough, wheezing, dyspnea) after manifesting penetration syndrome, but 20% have no ongoing symptoms.\(^5^3\) Many patients have a history of alarming symptoms followed by few ongoing complaints; an aspirated foreign body should not be dismissed from consideration in such patients. With dyspnea and odynophagia of sudden onset, subglottic impaction of the object should be suspected. If the object is known to be sharp and thin, the possibility that it has become embedded between the vocal cords or in the subglot-
tic region, with resultant partial obstruction, also should be considered.\[^{47}\]

Other components of the history may provide clues to airway foreign body presence and location. Even when the history cannot be obtained directly or does not suggest an aspirated foreign object, the presence of a foreign body can be inferred in certain patients. Trauma patients who present to the ED with injured, loose, or missing teeth may have aspirated in the field, or during emergency laryngoscopy and oral intubation.\[^{45}\]

Besides the intubated or obtunded patient with only indirect historical evidence of aspiration, conscious and alert patients may not give a direct history of aspiration owing to lack of dramatic airway symptoms or remoteness of the aspiration event and onset of secondary problems (e.g., pneumonia). In some cases, such as penetrating trauma or blast injuries, the patient may be unaware of the potential for aspiration and not attribute symptoms to this entity.\[^{42}\]

Patients who aspirate objects may have minimal or no symptoms, with chronic hemoptysis or odynophagia the only manifestation of these or similar foreign bodies.\[^{45,47}\]

The available evidence is conflicting regarding the role of neurologic disease in aspiration. Patients with deficits may be unaware of or unable to report problems such as denture displacement; this inability has been associated with disastrous results in the case of airway obstruction from dental hardware.\[^{43}\]

Neurologic impairment may result in atypical or absent history in cases of foreign body aspiration.\[^{42}\] Reports of adult and pediatric series have identified little role, however, for neurologic impairment in foreign body aspiration. An atypical history is a concern in neurologically impaired patients, but the problem of foreign body aspiration with atypical history is uncommon in this patient population.

Onset of respiratory difficulty after eating in a child can present a diagnostic dilemma. Children with stridor or other respiratory symptoms may have esophageal bolus impaction. The pediatric trachea is soft, especially posteriorly, and may be compressed by a large esophageal body pressing anteriorly on the trachea. In addition, the trachea itself may be displaced anteriorly and kinked, causing a partial obstruction.

Other components of the history can help diagnose and characterize foreign bodies in patients with aspiration of nonfood objects. These items may be aspirated by children who are exploring their environment, by psychiatric patients, or by persons who normally “store” small items in their mouths. The last group includes repairmen, construction workers, seamstresses, and others who may keep nails, pins, and other paraphernalia in the mouth for quick access.

Regardless of the nature of the foreign body, patients with a retained airway foreign object may present only with infectious complications. A foreign object may cause retropharyngeal abscess. With pathology located more distally in the airway tract, a patient with atypical or recurrent pneumonia may have pulmonary infection secondary to persistence of a foreign object serving as a nidus of infection. In some cases, the respiratory infection associated with retained pulmonary foreign body is silent but seeds distant organs with organisms, raising suspicion for an airway foreign body. In patients with Eikenella corrodens brain abscess, clinically occult respiratory foreign bodies have been found.\[^{52}\]

Patients may present to the ED with a diagnosis of a disease thought to be infectious but actually may have foreign bodies in the airway. A careful history should be obtained in the setting of suspected croup or epiglottitis because a foreign body in the trachea or larynx may have a clinical presentation similar to that with these infectious entities.

Physical Examination. Physical findings depend on degree of airway obstruction and duration of the object’s presence in the respiratory system. Small objects causing no obstruction may produce no findings or may manifest as infectious complications. In many cases, however, the physical assessment is helpful in diagnosis and characterization of airway foreign bodies.

Cyanosis is present in 10% and coughing, audible wheezing, or overt respiratory distress is noted in 25 to 37% of patients with aspirated objects.\[^{45,46}\] Unilateral diminution of breath sounds, when present, is a useful identifier of aspirated foreign body.\[^{50}\] Patients with upper airway foreign objects may be stridorous or hoarse, and sternal retractions may be noted in patients with intratracheal foreign bodies.\[^{40}\] More than one half of children in one series had initial oxygen saturation values of 95% or less.\[^{45}\] Patients with secondary infection may have fever.

Oropharyngeal examination may reveal a foreign body posteriorly or “donor sites” of fractured teeth. The examination should include a search for fractured or missing dental prostheses, which sometimes can be lodged in pharyngeal areas for days and can account for sudden deterioration in status when the airway suddenly becomes occluded, as can occur after coughing.\[^{51}\] Oropharyngeal examination frequently can be augmented by indirect or direct laryngoscopy or nasopharyngoscopy, but these procedures should be performed only if the associated stress is unlikely to pose undue risk of airway compromise. Furthermore, laryngoscopy or nasopharyngoscopy should be undertaken only if definitive airway management equipment and expertise are readily available. The advantage of these modalities is that they allow excellent visualization of the proximal airway, which is important diagnostically and therapeutically. Indirect laryngoscopy can be useful in detection of radiolucent structures.

Assessment of the neck may reveal accessory muscle use. Tracheal palpation may reveal a thud, indicating movement of a mobile foreign body against the tracheal wall. Abnormal inspiratory sounds may be heard on tracheal auscultation.\[^{42}\]

Coughing may result from local irritation caused by bronchial foreign bodies. Localized or apparently generalized wheezing is frequently auscultated in patients with lower respiratory tract foreign bodies.\[^{46}\] It is important to keep in mind the dictum that “all that wheezes is not asthma.” If a bronchus is completely obstructed, breath sounds are absent on the involved side. Occasionally a foreign body acts as a one-way valve, allowing air into the lung during inspiration but permitting none to exit during expiration. The involved lung becomes hyperexpanded, which may be detected as hyperresonance to percussion.

Diagnostic Imaging. In the stable patient, plain radiography of the neck and chest remains the mainstay of airway foreign body imaging.\[^{42}\] Air trapping may be shown when inspiratory and expiratory films are compared.\[^{46}\] Other imaging techniques of potential usefulness are fluoroscopy, CT, and MRI, although bronchoscopy and microlaryngoscopy (with an operating microscope) remain the ultimate diagnostic maneuvers.\[^{46}\]

A normal radiographic appearance cannot rule out an aspirated foreign body in a patient with a suggestive history. Series of patients undergoing endoscopy for suspected foreign body aspiration demonstrate mediocre sensitivity and specificity for plain radiography.\[^{43,45,50}\] The radiographic evidence is indirect (as discussed in the next paragraph) in most cases; radiopaque foreign bodies were found uncommonly (less than a fourth of patients on one series).\[^{53}\] This series included foreign bodies in the upper airway (at the level of the trachea); findings on plain radiographs in these patients frequently were negative.\[^{43}\]

If the radiopacities of the suspected foreign body is in doubt, and if the patient has brought a piece of the object, it may be
tested for radiodensity by placing it over the shoulder during taking of the radiographs. Specific findings on plain radiography are categorized as direct (i.e., identification of the foreign body itself) or indirect (e.g., hyperinflation). Direct foreign body identification is relatively uncommon. When subglottic foreign body impaction is suspected, plain soft tissue radiographic studies of the neck constitute the best initial step, provided that they are performed under the close supervision of a physician trained in provision of airway management. In some of these patients, plain radiography may definitively show an intratracheal foreign body and can provide a rapid diagnosis.

Indirect or secondary signs, such as narrowing of the subglottic space from an embedded foreign object, are an important aid in foreign body radiography. Air trapping and atelectasis are the most common early clues to presence of a foreign body in the airway, with bronchiecstasis and bronchial stenosis developing later. In air trapping, a comparison of inspiratory and expiratory films shows a flat, fixed diaphragm on the involved side, with shift of the heart and mediastinum to the uninvolved side during expiration (Fig. 57-6). In one pediatric series, air trapping was found in 90% of patients with lower airway foreign bodies, but it appears that indirect signs of airway foreign body are easily missed on initial interpretation of radiographs. The small caliber of the airways may explain the relatively higher frequency of air trapping in children compared with adult patients. If obstruction becomes complete, the involved lung becomes atelectatic; patients with persistent atelectasis should have foreign objects considered as the explanation. An additional indirect radiographic sign of more proximal foreign bodies is prevertebral swelling or soft tissue emphysema seen on neck films.

When a foreign body is seen on the chest radiograph but its exact location (airway or esophagus) is in doubt, the anteroposterior orientation of the object may help (Fig. 57-7). Esophageal foreign bodies usually are oriented in the coronal plane, with airway objects oriented in the sagittal plane (Fig. 57-8). Radiographs also can provide useful information by showing whether the object is within or outside of the tracheal air column (Fig. 57-9).

Fluoroscopy was used historically but has been largely supplanted by bronchoscopy as a result of advances in this modality. Fluoroscopy has identified air trapping, but one case series reported a relatively low 77% sensitivity for foreign body presence using this finding. CT, especially helical, is useful in evaluating patients with suspected airway foreign bodies when findings on plain films are negative. Even when an aspirated object is radiolucent, and often when the object cannot be identified by standard thoracic CT, helical CT has visualized the foreign body when it is of greater density than surrounding tissues. Helical CT can obviate the need for diagnostic flexible bronchoscopy, allowing direct progression to therapeutic rigid bronchoscopy for foreign object retrieval. CT also can be useful in delineating specific anatomic changes caused by foreign bodies. MRI may be useful in cases of aspiration of nuts, especially in children. The high fat content of the nut translates to its relatively easy visualization on MRI.

**Management.** Management of an airway tract foreign body is removal, which generally leads to rapid recovery of the patient. The emergency physician can accomplish removal in some patients. When the foreign object is distal to the oropharynx, however, subspecialty consultation is the safest and most expeditious means for foreign body removal. As a general rule, early bronchoscopy in any patient with a suspected foreign body is key to minimizing morbidity and mortality, and the role for endoscopic management remains important in light of limitations of other diagnostic methods.

A patient with critical airway obstruction and impending or actual respiratory arrest may require immediate and definitive intervention in the ED. The three management options in such cases are (1) to attempt to extract the foreign body with maneuvers, (2) to perform laryngoscopy with attempts at removal under direct visualization, and (3) to control the patient’s airway.

Some maneuvers to remove foreign bodies acutely are accomplished without direct visualization. These attempts may be directed at the proximal or distal respiratory tract. Proximal foreign body removal without direct visualization is attempted using the finger sweep, but this technique is losing favor in pediatric and adult patients. In infants, the larynx is higher, at the level of the fourth cervical vertebra; by age 4 years, it is at the C5–6 level. Blind finger sweeping has resulted in conversion of partial to complete airway obstruction when objects are displaced into the subglottic space. Finger sweeping also is less preferable in adults; abdominal thrusts and back blows are safer and at least as efficacious. These procedures produce increased intraluminal pressure in the trachea, thereby forcing objects out into the pharynx, from which they are easily removed.

The optimal management of a choking infant is controversial regarding whether back blows, chest thrusts, or abdominal thrusts should be the initial intervention. Data are limited, but
If indirect efforts fail to remove foreign bodies from patients in extremis, direct laryngoscopic visualization during intubation may reveal a proximal foreign object that can be removed with Magill forceps. If a foreign body is not visualized on laryngoscopy, intubation of the patient may be indicated. Intubation may force the foreign body distally, especially if the endotracheal tube tip is passed beyond the carina. Placement of the endotracheal tube into the right main bronchus may displace the foreign body into the right bronchus, allowing oxygenation and ventilation through the left-sided pulmonary tree when the endotracheal tube is withdrawn back to normal position proximal to the carina. In cases in which intubation fails because of positioning of the foreign object, surgical cricothyrotomy (needle cricothyrotomy in young children) is indicated. Cricothyrotomy may bypass proximal obstruction,
allowing sufficient oxygenation to bridge the time gap to definitive care by surgical subspecialists.

Patients who do not require immediate intubation or cricothyrotomy for complete airway obstruction may benefit from airway management for other indications. These patients may have poor oxygenation or may require assisted ventilations during transport to surgery. In either case, if airway obstruction is not too proximal or too complete, placement of a laryngeal mask airway should be considered. The laryngeal mask airway offers easy airway access, excellent visualization, and safe respiratory management during bronchoscopic procedures. The laryngeal mask airway allows use of larger bronchoscopes than those employed in intubated children. Especially in pediatric patients requiring bronchoscopy, the laryngeal mask airway may be an appropriate airway.45

In noncritical situations, the only airway foreign objects generally amenable to removal in the ED are those in the oropharynx, which are best removed by forceps under direct laryngoscopic visualization after topical anesthesia is achieved. Care should be taken when foreign objects appear to be impaled in the oropharynx because postremoval hemorrhage is a possibility. Also, special care should be taken to prevent posterior displacement of oropharyngeal foreign objects or dropping of incompletely grasped foreign bodies into the airway. These mishaps are more likely to occur in patients who are uncooperative; in these patients, subspecialty consultation for removal in the operating room is the best course. Removal of a laryngeal foreign object, even with the patient under general anesthesia, can be dangerous. Operative risks include hemorrhage, laryngeal trauma, and airway obstruction from the mobilized foreign object; subspecialty consultation also is indicated for laryngeal foreign body removal.47

The management decisions for endoscopic evaluation and treatment depend on the clinical presentation. An emerging standard is initial use of rigid bronchoscopy in time-critical airway obstruction, with flexible instrumentation used for diagnostic purposes in less acute situations.46 The emergency medicine specialist may have requisite expertise to perform flexible bronchoscopy in occasional low-risk cases, but consultants have broader experience, as well as facility with potentially useful adjuncts such as cinefluoroscopy.58 In patients in whom overall clinical suspicion is low, fiberoptic bronchoscopy may be indicated, but rigid bronchoscopy is the optimal first step when clinical suspicion is high.41 Foreign body removal usually is achieved using rigid bronchoscopy with the patient under general anesthesia, but in unusual circumstances, flexible bronchoscopy with use of local anesthesia may suffice for foreign body location and removal.45

Even after foreign body removal, late complications may occur. Injury from airway fish bones, even after removal, can lead to deep tissue infection, as well as facility with potentially useful adjuncts such as cinefluoroscopy.58 In patients in whom overall clinical suspicion is low, fiberoptic bronchoscopy may be indicated, but rigid bronchoscopy is the optimal first step when clinical suspicion is high.41 Foreign body removal usually is achieved using rigid bronchoscopy with the patient under general anesthesia, but in unusual circumstances, flexible bronchoscopy with use of local anesthesia may suffice for foreign body location and removal.45

Gastrointestinal Tract

Foreign bodies in the gastrointestinal tract can be seen in all age groups, although most cases occur in pediatric patients.60 No predisposing anatomic or pathologic conditions have been identified. Series have noted, however, that in addition to younger persons, those at highest risk include edentulous, incarcerated, and psychiatric patients.60-63

Complications associated with foreign body ingestion account for an estimated 1500 deaths annually in the United States.64 Perforation occurs in approximately 3% of cases and most frequently involves the esophagus or the ileocecal region.65 Because ingested objects are expected to pass spontaneously in the vast majority of patients with normal anatomy, initial management usually is expectant, with radiographic and stool follow-up examinations to confirm passage.65,66 Direct foreign body removal using surgical intervention usually is unnecessary, although some treatment centers pursue early operative intervention for impacted esophageal objects including coins.67 In pediatric series, endoscopy—including esophagoscopy, laryngoscopy, and anoscopy—tends to be successful in removing the foreign body in nearly all cases.66-68 Early endoscopy usually should be undertaken in cases of potential toxicity (e.g., button battery ingestion), altered anatomy (e.g., previous abdominal surgery), or sharp foreign bodies.

Pharynx and Esophagus

Foreign bodies lodged in the pharynx and esophagus are usually a sharp object (e.g., fishbone) that is impaled in the wall of the pharynx, hypopharynx, or esophagus or a larger bolus, usually a coin or food, that cannot pass beyond the anatomic points of esophageal constriction. Pediatric series analyzing both witnessed and unwitnessed ingestion of esophageal foreign bodies report that coins are the most common culprit, typically accounting for more than one half of the cases.66,67 Esophageal constrictions, where foreign objects tend to lodge, are (1) the proximal esophagus at the level of the cricopharyngeal muscle and thoracic inlet or, radiographically, the clavicular level; (2) the midesophagus at the level of the aortic arch and carina; and (3) the distal esophagus just proximal to the esophagogastric junction, or radiographically a level two to four vertebral bodies cephalic to the gastric bubble. Foreign bodies may lodge at any level of the esophagus (or remainder of the gastrointestinal tract) with abnormal anatomy. The complication rate for esophageal foreign body ingestion is estimated at less than 2%, but the sequelae can be severe. Complications become more likely with increasing impaction time and include esophageal erosion or perforation, tracheal compression, mediastinitis, esophagus-to-airway or esohagus-to-vascular fistulas, extraluminal migration, and formation of strictures or false esophageal diverticula.57-59

History. A useful history usually is available from the patient or a caregiver. Because natural curiosity leads them to ingest myriad nonfood items, children are particularly likely to present with esophageal foreign bodies. The object most often encountered is a coin.66,67 Other common objects are foods, toys, bones, batteries, wood, and glass.60,71 In a series of 104 consecutive cases, one third of the esophageal foreign bodies were sharp objects.64 In situations in which the history is unclear, ingested foreign body should be considered in the differential diagnosis for atypical chest pain.72

Esophageal rupture is a particular risk with ingestion of a button (disk) battery.3 These batteries cause pathologic changes through pressure, electrical current, corrosive leakage, or heavy metal poisoning.66 Batteries containing potassium can produce liquefaction necrosis, and batteries containing mercury can cause mercury poisoning.73 The identification of button batteries has both prognostic and therapeutic ramifications—esophageal button battery impaction is an indication for prompt endoscopic intervention.66 Although not as likely as button batteries or sharp foreign bodies to cause esophageal rupture, practically any ingested foreign body (e.g., meat) can cause rupture if patients experience repeated vomiting after impaction.74
Retention of an ingested object in place for longer than 24 hours is more likely to cause mucosal erosion, and management plans for ingested bodies are different when the objects have been in the gastrointestinal tract for a long time. Children usually present to the ED within 6 hours of foreign body ingestion. The most frequent presenting manifestations are dysphagia, drooling, retching, and vomiting. Pain, usually odynophagia, may be the major complaint. Anorexia, wheezing, and chest or neck pain also may be features. Patients may complain that they can feel the object in the throat or chest and are unable to pass it any further. The victim often is able to localize the foreign body accurately, particularly in the upper esophagus, and should be asked to indicate the level of obstruction. Drooling is consistent with high-grade obstruction. Patients rarely may complain of shortness of breath or air hunger resulting from a large foreign body in the esophagus impinging anteriorly and compressing the trachea. Infants and children may experience coughing, choking, and significant respiratory compromise from foreign bodies lodged in the upper esophagus.

Patients may present with late sequelae. Foreign bodies serving as a nidus for infection result in complaints (e.g., fever) consistent with the infectious process. Signs of mediastinitis indicate esophageal perforation. Perforation of the esophagus with erosion into the vasculature or pulmonary tree can result in presentations ranging in severity from hemoptysis to pulmonary abscess to life-threatening hemorrhage.

The history should include any known esophageal anatomic abnormality or previous instrumentation. A patient with a history of esophageal stenting should be considered to have stent migration when the presenting complaint is dysphagia. Migration typically occurs within the first week of placement but has been reported up to 1 year after initial placement. 

Physical Examination. Examination begins with a careful search of the pharynx and hypopharynx. This search may reveal the foreign body or identify an oropharyngeal mucosal scratch that can cause foreign body symptoms even in the absence of an impacted object. Oropharyngeal examination also may provide indirect clues; for example, a missing dental plate should suggest the possibility of its presence as a gastrointestinal tract foreign object. The base of the tongue, vallecula, supraglottic area, epiglottis, and piriform sinus should be examined. Topical anesthesia facilitates the examination. If adequate visualization is not obtained with the indirect laryngoscopy mirror, fiberoptic nasopharyngoscopy or direct laryngoscopy should be performed.

Subcutaneous emphysema found by neck palpation indicates probable esophageal perforation. Drooling and inability to handle secretions are secondary indicators of esophageal impaction; wheezing can be a manifestation of airway compression. Esophageal object detection generally necessitates esophagoscopy, however, because these foreign bodies are not otherwise amenable to detection by physical examination.

Diagnostic Imaging. Because of the limitations of clinical presentation and examination in excluding a foreign body, radiography is a routine part of the assessment and contributes to diagnosis and management in approximately one half of the cases. The initial step generally is to obtain posteroanterior and lateral chest radiographs and lateral cervical spine films made using soft tissue technique. The primary utility of plain radiography lies in detection of radiopaque objects, although some series report that retrospective review of lateral neck films identifies indirect signs (e.g., soft tissue swelling) in most patients with proximal aerodigestive tract foreign body. Overall, the sensitivity of plain radiography for detection of esophageal foreign bodies is relatively poor. Plain radiography has identified metal foreign objects missed on direct (including endoscopic) examination, however. In patients who are transferred to the ED from an outlying hospital, repeat radiography may be useful to assess whether the foreign object has passed into the stomach in the interval since previous studies. Plain films of the neck and chest have sensitivity of roughly 25% for impacted fish bones. Although some studies suggest that technique variation improves fish bone detection, plain radiographs remain insufficiently sensitive as a means to rule out these foreign bodies. In various studies, false-negative results were reported in at least 30 to 55% and false-positive results in approximately one fourth of the cases.

When plain films fail to visualize foreign bodies and suspicion remains high, one option is contrast esophagography, which can be useful with radiopaque and sometimes with radiolucent foreign bodies. If perforation is not a concern, barium may be used as the contrast medium because it provides higher-quality images. If an esophageal leak is suspected, water-soluble contrast solution should be used; a barium follow-up study may be considered if findings on the initial contrast study are equivocal or suspicion remains high. When initial contrast films are not definitive, patients may be asked to swallow a contrast-soaked cotton ball, which may localize the foreign body by lodging proximal to the object. Contrast studies, even when performed with barium, have limitations when the suspected object is an impacted bone. In one series using barium-soaked cotton balls, false-positive and false-
negative rates were 26.9% and 40%, respectively. Barium swallow yields better results but risks aspiration and coats the object and esophagus, reducing effectiveness of subsequent endoscopy. CT scans with coronal and sagittal reconstructions are useful in identifying foreign bodies or in further characterizing objects seen on plain films. CT has been recommended as the primary diagnostic modality because it can give information about foreign body size, type, location, and orientation with respect to other anatomic structures. In one study, non–contrast-enhanced CT scans interpreted by resident physicians detected all impacted bony foreign bodies found by esophagoscopy; the one false-positive result was due to esophageal calcification, and no false-negative results were reported. Overall, CT use reduced the incidence of negative results on esophagoscopy. These study findings potentiate a potentially important role for CT in imaging of impacted bony foreign objects. CT also can assist with identification of complications. CT identified a fistulous (subsequently fatal) esophagogastric tract in a patient who had swallowed a bone splinter 1 week earlier. Also, CT may be used in patients with positive findings on plain films and negative results on esophagoscopy to search for objects that have migrated from the intraluminal to the extraluminal space.

A relatively inexpensive and noninvasive modality reported to be useful in detection and characterization of metal foreign bodies is scanning with a hand-held metal detector. Use of a commercial hand-held metal detector (e.g., Super Scanner, Garrett Security Systems, Garland, Texas) has been studied in large adult and pediatric series of patients with suspected esophageal metallic foreign bodies, with positive and negative predictive values approximating 90 to 100% (and no complications). The hand-held metal detector easily detects aluminum foreign bodies missed by radiography. The hand-held metal detector avoids time, radiation exposure, and costs associated with radiography and may obviate the need for radiography in patients with suspected coin ingestion in whom no foreign body is detected or an object is detected below the diaphragm.

Management. Pharyngeal foreign bodies visualized by direct or indirect laryngoscopy usually can be removed with a forceps or clamp. It is important to guard against the possibility of inducing trauma as well as airway obstruction during extraction attempts.

Management of esophageal foreign bodies depends on many factors. With esophageal food bolus or coin, the emergency physician often can provide appropriate treatment. With sharp objects, displaced esophageal stents, or impacted button batteries, more invasive techniques are necessary. Management strategy depends on the nature of the foreign body, the length of time the object has been lodged, and the expertise and experience of the treating clinician. In addition, the patient's age and previous medical and surgical history may be relevant. The overall success rate for nonsurgical removal of objects from the esophagus is greater than 95%. The first basic strategy for esophageal foreign body management is applicable only if the object is known to be an impacted food bolus. In these cases, pharmacologic maneuvers may be tried to move the bolus into the stomach. Glucagon (0.5–2 mg) given intravenously has been used to relieve distal food obstructions. The drug acts by lowering the smooth muscle tone at the lower esophageal sphincter without inhibiting normal esophageal peristalsis. A concern is that too-rapid administration of glucagon may cause vomiting, posing a risk of rupture of an obstructed esophagus. Other pharmacologic agents have been used with mixed success. Gas-forming agents also have been used, and although supporting evidence is sparse, some practitioners suggest that this approach should be attempted first or in combination with glucagon. Patients who complain of chest pain at presentation should not be given gas-forming agents because they may have esophageal perforation. Two other agents used for management of distal food bolus impaction that probably are not as useful as glucagon are nitroglycerin and nifedipine. Both of these agents have a relaxing action on the lower esophageal sphincter and are safe and roughly equally (if only marginally) effective agents for management of impacted food bolus. A last approach, enzymatic degradation of an impacted meat bolus using the proteolytic enzyme papain, has fallen into disfavor because of risks of esophageal perforation.

The preferred strategy for esophageal foreign body removal is endoscopy. Flexible endoscopy does not require general anesthesia, can be performed in a sedated (nonintubated) patient, and may be both diagnostic and therapeutic in the case of foreign bodies such as coins. The high overall success rate for endoscopy has prompted some experts to recommend that patients with symptoms that started within 48 hours of ED presentation be taken directly to the endoscopy suite if no suspected complication is evident.

Another removal strategy, best suited for smooth, nonimpacted, and blunt objects, uses a contrast-filled balloon catheter and fluoroscopy. A Foley catheter is introduced into the esophagus, and the balloon is inflated with radiographic contrast material, and withdrawn under fluoroscopic monitoring; the object is extracted along with the catheter. To minimize risk of foreign body aspiration, this procedure should be performed with the patient in a steep, head-down position in lateral decubitus; the procedure is contraindicated in patients with airway compromise, complete esophageal obstruction, or inability to cooperate.

The final strategy for active foreign body removal, bougienage, involves pushing the foreign object into the stomach. Strict criteria determine eligibility for this procedure, which generally is not performed by the emergency physician. Compared with endoscopy, bougienage appears to be at least as safe and much more time- and cost-efficient. Although patient eligibility for bougienage may be limited by factors such as presentation delay, when performed, the procedure appears to be successful in up to 95% of attempts.

The fifth approach, expectant management awaiting spontaneous passage of the foreign object into the stomach, is often successful. This approach is best for patients presenting within 24 hours of ingestion and who have a radiographically identified “safe” (e.g., coin) object in the distal esophagus. The button battery is associated with specific expectant management issues. If a disk battery has been ingested, its location must be ascertained, with immediate removal if it has lodged in the esophagus. If the button battery has passed distal to the esophagus, the patient can be observed, with serial radiographic follow-up studies to confirm spontaneous passage through the gastrointestinal tract.

After the removal of an esophageal foreign body, regardless of the method used, a follow-up esophagogram frequently is necessary to evaluate esophageal anatomy and patency. Referral to investigate cause of dysphagia and obstruction should be made.

Stomach and Bowel

Foreign bodies that reach the stomach rarely cause major difficulties, although problems such as perforation may occur even with ingestion of blunt objects. Observation with expectant management usually is appropriate because ingested foreign bodies reaching the stomach generally are
propelled by peristalsis through the length of the gastrointestinal tract, with expulsion in a few days. Objects may pass beyond the esophagus and still become impacted, however, most often at the gastric outlet or the ileocecal valve, although complications can arise at any point throughout the intestinal portion of the gastrointestinal tract.96,97 If the foreign body is a bezoar, a mass of undigestible food or nonfood material, a palpable mass may be noted on abdominal examination. Otherwise, the physical examination is relatively unhelpful, only rarely revealing indirect evidence of foreign body presence or complications.

History. Signs and symptoms of intraluminal objects range from none to vague abdominal pain to obstruction or perforation-associated peritonitis.97 Most patients have a specific history of ingesting a nonfood item, however, or the circumstances indicate the likelihood and character of an intestinal foreign object. Patients with psychiatric or secondary-gain reasons for foreign body ingestion occasionally may be encountered in the ED.

Hiding of illicit drugs is an important motivation for foreign body ingestion. Rupture of these drug-containing packets, especially when cocaine is involved, may have rapid and fatal consequences. Less often, one or more packets can cause bowel obstruction. Even when obstruction is not present, vomiting may be reported. Body packing, which entails systematic gastrointestinal tract placement of previously prepared drug packets (Fig. 57-11), should be clinically differentiated from body stuffing, which denotes hurried ingestion of hastily prepared packets in the face of imminent police presence.98 Body stuffers are more likely to experience toxicity because of the poor packaging of drugs and are less likely to exhibit positive plain radiography findings.99 Drugs most often involved in body packing or body stuffing are cocaine and heroin, with amphetamines and cannabinoids involved less frequently.

Another important component of the history is placement of a dental implant or of a medical implant in the gastrointestinal tract. Dental implants can migrate to the distal gastrointestinal tract, where they may cause complications.79 Expandable esophageal stents migrate in some patients, and biliary stents also have become malpositioned, with resulting complications.100

Patients with gastrointestinal tract foreign bodies should be asked about history and behaviors possibly related to the development of bezoars. A habit of chewing hairs can result in formation of trichobezoars, which infrequently extend from the stomach into the small intestine as a “tail” (Rapunzel syndrome). Phytobezoars (composed of vegetable matter) and lactobezoars (from milk curds) also have caused complications, usually in the stomach.101 Infants with lactobezoars from undigested formula may have a history of prematurity and often are receiving formulas with a high casein-to-whey ratio. Other bezoars may be composed of infectious (e.g., fungal bezoar) or inorganic (e.g., lithobezoar) material.102

Other specific intestinal foreign bodies, previously mentioned in the discussion of esophageal impaction, are of clinical importance in the distal gastrointestinal tract. Button batteries can rupture in the intestine, and fish bones have penetrated through the gastric mucosa. Ingested toothpicks can lodge in the bowel wall, causing gastrointestinal complications and erosions or compression of nearby structures.88

Diagnostic Imaging. The initial imaging modality is plain radiography, which often is diagnostic (Figs. 57-12 and 57-13). Two-view plain radiography has proved useful in clinical situations ranging from coin ingestion to body packing (see Figs. 57-10 and 57-11). Plain radiographic findings are positive in approximately 90% of body packers but are nearly always negative in body stuffers and usually are negative in patients who have ingested crack vials.99,103,104 Plain radiography usually identifies drug packets, but false-negative results do occur, and follow-up contrast radiography or CT is recommended.105 Ultrasound imaging has been reported to be useful in drug packet cases in which plain radiography is nondiagnostic, but this modality is most helpful when it yields positive findings (i.e., a negative result is insufficient to rule out presence of an ingested packet).106

Figure 57-11. Plain radiograph obtained in a patient after body packing. Note the appearance of previously prepared drug packets.

Figure 57-12. Plain radiograph obtained in a child who had ingested a fishing lure (without hooks).
Contrast-enhanced upper gastrointestinal tract radiography has intermediate success in patients with suspected body stuffing or body packing. Contrast administration also has proved useful in outlining bezoars. CT can identify foreign bodies in the stomach and intestines and can help diagnose packet ingestions in body stuffers. In these patients, contrast-enhanced CT outlines the bag containing the illicit drug; contrast administration also can help by identifying air trapped in the packet. CT has yielded false-negative results, however, in detection of drug packets. CT also has proved useful in determining whether complications of foreign body perforation are present.

Management. The general rule for the management of gastric or intestinal foreign bodies is observation, although some treatment centers favor early endoscopy and report this approach to be nearly universally successful. Management decisions are based in part on the nature of the ingested object. Blunt objects can be expected to pass easily through the bowel, with expulsion verifiable by stool examination. If confirmation of passage is of particular concern, serial radiographs may be obtained after 5 to 7 days. Sharp objects may be recovered using fiberoptic gastroscopy, although they traverse the gastrointestinal tract without incident in 90% of cases. Early removal generally is required for objects wider than 2 cm because they do not pass the pylorus, or for those longer than 5 to 6 cm because they do not clear the duodenal sweep. Overall, surgery is required in less than 1% of cases of intestinal foreign body, but in certain instances (e.g., bowel obstruction), clinical circumstances prompt early operative intervention.

When chosen, observation should be continued until (1) the object is found in the patient’s stool; (2) the object causes bowel obstruction or perforation, requiring immediate surgical intervention; or (3) the object shows no evidence of progression through the gastrointestinal tract on two radiographic examinations performed 24 hours apart, indicating impaction and mandating active removal. In some cases, the identity of the foreign body dictates management. In a body packer or body stuffer, regardless of external (e.g., law enforcement) pressures, only interventions that are justified medically as reasonable steps to prevent injury from the ingested object or substance should be performed. If urgent drug packet retrieval is unnecessary, the patient should be admitted for close observation for packet passage or signs of toxicity. Monitoring of drug levels can be helpful. Usually the packet passes through the gastrointestinal tract spontaneously. This passage can be facilitated with polyethylene glycol solution or laxatives or both. If cocaine-containing packets have been ingested, alkalinization of gastric contents (to enhance hydrolysis of cocaine to its inactive metabolite benzoylecgonine) may be of therapeutic assistance.

Immediate removal of drug-containing packets should be considered in patients in whom intestinal obstruction or drug intoxication develops. Most experts, citing risks of packet rupture and drug toxicity, contend that endoscopic removal of cocaine-containing packets is never indicated. Endoscopic removal has been reported to be safe and effective, however, in an asymptomatic patient who ingested a single packet.

As noted earlier, button batteries represent another foreign body type with specific management implications. Intact batteries ingested into the stomach can be observed without the immediate removal necessary in cases of esophageal impaction. Repeat radiographs should be taken the next day to ensure movement of the battery into the intestinal tract, with films obtained every 3 to 4 days thereafter to confirm continued distal movement. As with illicit drug-containing packets, administration of polyethylene glycol solution may speed distal movement. If the foreign body has not been passed after the first few clear liquid stools, repeat radiography may identify the battery in the rectum, where it may be digitally evacuated. Surgery is indicated for failure of the battery to progress, for radiographic signs of battery rupture, or for development of symptoms such as abdominal pain. Endoscopy is increasingly reported to be useful for removal of gastric button batteries, with success in 14 of 16 cases in one series (the other two batteries were endoscopically moved into the intestine and subsequently were passed spontaneously).

Management of bezoars depends on type and location. Dietary therapy, endoscopic removal, and enzymatic dissolution frequently are used. For some bezoars, specific therapy has been identified. Infants with lactobezoars should be changed to elemental diets and observed, because most cases resolve without surgery.

Rectum

Most anorectal foreign bodies result from retrograde introduction, typically as a result of sexual practices that patients may be reluctant to discuss. Obtaining the history also may be difficult owing to presence of a mental disorder, reported in more than one third of patients with rectal foreign bodies in an 8-year series. Prompt diagnosis is crucial because delay in definitive treatment is strongly associated with complications.

History. Patients with anorectal foreign bodies often are hesitant to give an accurate history. Studies have found that many patients with self-introduced anorectal foreign bodies do not initially admit to insertion but rather present with anal pain or simply constipation (which is in fact the most common complaint). Other complaints include rectal pain, bleeding, and inability to void when large objects impinge on the urethra. History also may be lacking in body packers, who may present with toxicity symptoms; fatal cardiovascular collapse can occur with ruptured cocaine packets.

It is possible for ingested food or objects to lodge in the rectum after passing through the proximal gastrointestinal
tract. Rectal foreign masses of fish bones have been noted in many patients, all of whom strenuously denied transanal insertion, and in a series characterized by a high proportion of mental patients, oral ingestion accounted for nearly half of the of rectal foreign bodies. If patients do admit to transanal foreign body placement, more accurate information about size, shape, and physical characteristics to plan imaging and extraction may be obtained. The duration of retention of the object in the anorectum has implications for mucosal failure and rupture.

**Physical Examination.** In patients with anorectal perforation, examination may reveal evidence of peritonitis or abdominal tenderness. On digital rectal examination, the foreign body may be directly palpated; this is the method of diagnosis in a large number of cases. In the absence of direct foreign body palpation, findings on digital rectal examination (e.g., bloody discharge, loose sphincter tone) may raise suspicion for anorectal foreign body.

When findings on digital rectal examination are negative or when better visualization is required, anoscopy is the next step. Although the anoscope’s diameter limits the size of foreign bodies that may be extracted through the instrument, anoscopy affords an improved view of the nature and positioning of the object. Similarly, rigid sigmoidoscopy may be performed, with special care taken to minimize pressure on possibly ischemic anorectal mucosa. In many patients, especially those in whom multiple examinations or removal attempts have been made, sedation and analgesia may be required to enable invasive examination techniques. With any doubt about the integrity of the anorectal mucosa, invasive examination is best done in the operating room with the patient under general anesthesia.

**Diagnostic Imaging.** The foreign body may be detected on a plain abdominal radiograph (Fig. 57-14; see also Fig. 57-16). An important secondary finding is free intra-abdominal air secondary to anorectal perforation. If the object is not visualized on plain films, a contrast study can be performed, with care taken to minimize hydrostatic pressures on potentially compromised mucosa. Water-soluble contrast material should be used if perforation is suspected. Specialized imaging such as CT is not usually part of the imaging workup but may be indicated if complications are suspected.

**Management.** With patience and judicious use of sedation and analgesia, the emergency physician often can remove rectal foreign bodies. Surgical intervention may be necessary on occasion and was in fact required in a majority of patients in some series. Depending on the nature of the foreign body and the presence of damage or perforation of the rectal wall, transanal removal (with or without sedation and local anesthesia) is successful in roughly half of the patients, with general anesthesia required in the remainder. Attempts to retrieve objects that pose a high risk for rectal injury due to sharp edges or likelihood of dangerous breakage (e.g., lightbulbs) are not recommended.

Initial efforts at foreign body removal in the ED should begin with the examiner’s digit. Small rectal objects occasionally can be hooked by a finger and withdrawn; this is the initial technique in patients who do not have signs of peritoneal irritation from bowel wall perforation. The digit should be lubricated with lidocaine jelly, and abdominal pressure may be applied in an attempt to mobilize foreign objects distally.

When digital extraction fails, an anoscope or small vaginal speculum can be used in an attempt to visualize the foreign body. A ring forceps is placed through the visualizing apparatus to grasp and remove the object. Sometimes the mucosa may become tightly adherent to the distal end of the foreign body, creating a vacuum that prevents object withdrawal. Passage of a Foley catheter beyond the foreign object (sometimes through a rigid sigmoidoscope) with proximal air inflation usually breaks the vacuum and permits retrieval. Passage of the catheter, followed by air inflation and balloon filling, may allow object removal with gentle catheter traction.

When the appropriate expertise and equipment are available in the ED, or if subspecialists are available for consultation, the next step may be removal with a vacuum device, well suited for use with some foreign bodies (Figs. 57-15 and 57-16), or with forceps; sigmoidoscopy may be a necessary adjunct to such an approach. As with other removal means, careful technique is essential to minimize risk of anorectal perforation. Removal of occult anorectal foreign objects after administration of an enema for symptomatic relief of anal pain was successful in 10% of patients in one series. Experts caution against possible perforation, however, when enemas or cathartics are...
administered to patients with known rectal foreign bodies, especially those with sharp edges.

After removal of the foreign object, the possibility of rectal trauma should be considered. When foreign body retrieval has been simple and the patient does not show increased pain, tenderness, or rectal bleeding, further evaluation for rectal trauma probably is unnecessary. If any of these is present, postremoval sigmoidoscopy may identify small abrasions requiring close follow-up, but generally hospitalization is necessary only if a rectal laceration or perforation is found. An appropriate antibiotic regimen is indicated in all cases of suspected bowel wall perforation and peritonitis. Long-term follow-up study has identified few or no sequelae in patients with rectal foreign bodies.108 In one study tracking patients for more than 5 years, the investigators found no problems with fecal incontinence or recurrence of rectal foreign objects.111

**Genitourinary Tract**

The literature describes a wide variety of genitourinary tract foreign objects, ranging from easily extracted tampons and condoms to penile rings removed only with great difficulty.112,113

**History.** An accurate history may not be readily obtained because most foreign bodies are placed by the patients themselves. Reports have validated the occasional value of a history, however, as a means to diagnose some genitourinary objects such as those associated with genital body piercing (in patients or their sexual partners).114,115 In children who fear parental disapproval of foreign object placement, secondary signs constitute the usual presentation. They are brought to medical attention when parents note foul-smelling, purulent discharge or bleeding from the urethra or vagina or both.116 Another common infant presentation is penile constriction caused by inadvertent wrapping of hairs around the shaft, usually just proximal to the corona.117

In older children, rubber bands or string may be placed around the genitalia. In adolescents and adults, metal objects are placed for autoerotic stimulation. Constricting bands may be placed proximal to the scrotum or, more often, on the penile shaft. These patients frequently have presentations delayed by 12 hours or more. The swelling that renders these constricting bands so difficult to remove also hinders the physical examination, emphasizing the need for an accurate history.117

Occasionally an inserted object (e.g., a tampon) is forgotten until it causes purulent discharge. Secondary symptoms also can bring foreign bodies to medical attention in rare cases of genitourinary tract perforation by foreign bodies from the genitourinary tract or elsewhere. Migration of an intrauterine device into the bladder has occurred, with associated cystolithiasis. In another unusual case, a sewing pin caused perforation through the appendix and into the bladder.

Genitourinary tract foreign bodies may be infectious. The term bzoar, traditionally considered to delineate indigestible material in the gastrointestinal tract, also has been used to describe foreign collections in the bladder. A common urinary tract bzoar is the Candida bzoar, seen in immunodepressed patients or in patients with diabetes mellitus, neurogenic bladder, antibiotic use, or an indwelling urinary catheter.118

**Physical Examination.** Patients of all ages require a careful, gentle examination because they often are anxious about the anatomic region being examined. In a pediatric patient, a nasal speculum may be used to help visualize a vaginal foreign body. A vaginal foreign body may be palpated during digital rectal examination.

In children and adults, the presence of blood or discharge at the urethral meatus or vagina should be noted. Patients with intraurethral foreign objects also may have perineal induration and a high incidence of associated infection, which may progress to sepsis syndrome.112 In males with penile shaft swelling, careful inspection for constricting objects is indicated. In an infant with penile swelling, a coronal constricting hair should be sought.117

In patients with penile rings, especially most who present after some hours’ delay, examination may reveal a swollen penis with mottling, dusksiness, and excoriation. The interruption of venous and lymphatic outflow results in increasing penile enlargement with the risk of tissue damage. Damage is especially likely if the patient previously has tried removal of the constriction.117 Urethrococutaneous fistulas, relatively common in infants and children, should be sought in any patient with a constricting band.

Examination may reveal only indirect evidence of other genitourinary objects as well. Multiple abscesses in an enlarged scrotum have been reported in a patient presenting with acute infection from embedded metallic objects placed (by the patient) decades before ED presentation.114 Any genitourinary examination abnormalities should prompt questioning of the patient about possible foreign bodies.

**Diagnostic Imaging.** Often, no imaging is necessary, but plain films may be obtained to look for urethral or bladder radiopaque foreign bodies. Plain radiography also has proved useful in unusual cases of embedded metallic objects not palpable because of pain.114 Urethrocytography may be useful in identifying and locating genitourinary tract foreign objects and has been an aid to surgical planning for affected patients.112 Intravenous urography may reveal a filling defect in the case of a bladder foreign body, or it can reveal delayed renal excretion as a general finding suggesting foreign object–related renal function impairment. Ultrasound imaging is useful to investigate for hydronephrosis. Acoustic shadowing may or may not be seen, depending on the nature of the foreign body: Candida bzoars, for example, do not produce acoustic shadowing. These bzoars and other genitourinary tract objects generally are identifiable on CT.118

---

**Figure 57-16.** Plain radiograph obtained in a patient who had inserted an aerosol can into the rectum.
Management. Vaginal foreign bodies usually are removed easily. If the object has been present for some time, any associated vaginitis should be treated. In males or females, foreign bodies located just inside the urethral meatus usually can be grasped with a clamp and removed. The overriding goal is to avoid causing further damage to the already traumatized urethra. After failure of one or two attempts at removal in the ED, the best course is early consultation with the appropriate subspecialist. Objects located in the proximal urethra or bladder usually require cystoscopy for extraction. One exception is the Candida bezoar, for which management generally consists of treatment with antifungal agents.116 Penile urethral foreign bodies may be associated with urinary retention and secondary infection; early endoscopic intervention is necessary for these patients.113

Constricting penile foreign bodies must be removed as early as possible because progressive swelling makes removal more difficult. Sedation and analgesia may be necessary. Also, care must be taken in removing constricting objects with instruments such as ring cutters; penile shaft lacerations may result because of the tautness of the thin underlying skin. Hair and string foreign bodies are removed relatively easily with forceps and scissors or scalpel. Wrapping the penis with string followed by distal mobilization of the ring (as is done for digital foreign bodies) has been successful.117 Other approaches have been used to remove penile constricting bands. A cast saw, the vibrating blade of which reduces risk of skin damage, may be used for removal of some objects, such as acrylic rings. After penile ring removal and confirmation of ability to void, patients usually can be discharged with close follow-up.117 Subspecialty consultation should be obtained for patients with penile trauma.

Soft Tissues

Soft tissue foreign bodies present unique diagnostic and management dilemmas. Foreign bodies may be present not only in patients with known wounds but also in patients with secondary symptoms who are unaware of or uncertain about foreign body entry.

History. All patients with wounds should be considered for soft tissue foreign body contamination, and evaluation of soft tissue injury should include a search for foreign objects. In straightforward cases, patients present with symptoms such as pain or foreign body sensation and may report presence of a specific foreign body. In more difficult cases, patients present with symptoms related to complications. Soft tissue infections, especially recurrent, should suggest a foreign body serving as a nidus. Careful history in patients with soft tissue complaints should include a search for antecedent trauma, no matter how remote, which may have resulted in foreign body entry.

Physical Examination. The diagnosis frequently is obvious on visual inspection or standard wound evaluation. For smaller objects, use of loupe magnification may be a significant aid in foreign body identification and removal.119 Besides location of the foreign body, the examination should assess for injuries collateral to the object’s presence. Distal neurovascular function should be tested.

Diagnostic Imaging. Anteroposterior and lateral radiographs of the involved area of the body are valuable. Plain radiography has been shown to be more than 98% sensitive when the foreign body is metal or another radiopaque material, such as gravel.120,121 If silver nitrate sticks were used to achieve hemothasis before imaging, the deposited metal can be expected to appear on plain radiographs.121

One common foreign body is glass, which has shown radiopacity.120,121 In one cadaver study, nonleaded glass was visualized with 90% sensitivity and a false-positive rate of 10%; glass color and location were unimportant, but a volume of less than 15 mm³ was associated with a greater likelihood of failed visualization.122 Other items are not easily seen on plain radiographs, which are insensitive for detection of vegetable (e.g., wooden) material or plastic objects.120,121 Xeroradiography, recommended in the past, has no advantage over plain radiography and has been discarded in favor of other modalities (e.g., CT) when plain film findings are negative and suspicion remains.120,121,123 In EDs in which digital radiography and image manipulation are available, the use of “soft tissue” exposures is not necessary. For EDs in which hard-copy radiographs are used, specification for “soft tissue” exposure should be indicated when films are requested.

Fluoroscopy has received attention as a diagnostic and therapeutic tool. In an ex vivo beef model, emergency physician–conducted fluoroscopy had 100% sensitivity for gravel, metal, and glass; sensitivity was 90% for graphite and zero for plastic and wood.124 Another evaluation of C-arm imaging in a chicken leg model also found 100% of gravel, metal, and glass objects, although sensitivities for wood and plastic were low.125 One advantage of fluoroscopy is that it can guide removal and later confirm absence of foreign objects.

When plain radiographic findings are negative yet suspicion for foreign body remains, ultrasound imaging or CT is the next step.123,126,127 Ultrasonography is readily available in many EDs and has been the subject of intensive but ultimately unconvincing study. Even radiologists, interpreting scans done in an animal model, had low detection rates for gravel (40%), metal (45%), glass (50%), cactus spine (30%), wood (50%), and plastic (40%); overall, false-negative and false-positive rates were 50% and 30%, respectively.126 In another study, using a cadaver hand model, ultrasound imaging proved 93% sensitive for wood and 73% sensitive for plastic foreign bodies, but specificity was only 59%.128 A third study, using credentialed sonographers and radiologist interpretations in a chicken breast model, found some utility for ultrasound imaging in the ED. The investigators concluded that a 7.5-MHz probe was better at shallow depths and that a 5-MHz probe should be used for deeper searching.129 The study found that wood had the best acoustic shadow, followed by plastic; other materials investigated (paper clip, glass, needle) had lesser shadowing and were more difficult to detect. In another artificial setting, ultrasound imaging was the only modality among plain radiography, CT, and xeroradiography that clearly identified wood and plastic foreign bodies.130 Overall, in view of the general availability of ultrasound imaging in the ED and the case reports of its clear occasional utility in foreign body localization and removal, it is reasonable to use this technique with the understanding that a positive test result is much more useful than a negative one.131,132

In addition to characterizing objects seen on plain films, CT is useful for detecting items (e.g., plastic, wood) not evident on plain radiographs.123,125,127 CT also is valuable in localizing small or deep objects and delineating anatomic positioning.123,126 Newer-generation image viewers increase the utility of CT; higher detection rates for wood and plastic are reported with on-screen image viewing and manipulation than with hard-copy CT film.133,134 CT also is useful for identifying foreign body sequelae (e.g., abscess).

MRI can assist in identifying foreign body complications.126 Soft tissue objects can induce a chronic inflammatory reaction and lytic or blastic osseous changes that allow MRI localization.135 In other cases, MRI is less useful. Gravel, readily detected on images obtained with most modalities, causes MRI streaking because of ferromagnetic material. MRI also has identified foreign objects of wood and plastic; however,
CT usually is adequate for detection of these types of foreign bodies.\textsuperscript{121}

Management. The most important determinant of successful foreign body removal is knowledge of the object’s precise location. Standard radiopaque markers can aid in wound localization. For small objects, needles placed in the soft tissues can help pinpoint the location of foreign bodies seen on radiographs. Fluoroscopy may allow simultaneous visualization and removal. When objects are not radiopaque, judicious probing of wounds with fine-gauge needles or forceps may allow tactile detection of the foreign body.

To remove a foreign body, it may be necessary to extend the original wound or, if it is located away from the entrance site, to make a separate incision. The emergency physician can retrieve the foreign body from the soft tissues and palpate the object’s location. Standard radiopaque markers can aid in wound localization. A Knowles retractor or similar device may allow biopsy forceps to be used. With careful dissection, the foreign body can be removed intact. If the object is too large to be withdrawn, it may be necessary to isolate the object with a towel clip, then incise the overlying soft tissues and remove the object in toto. The proximal end of the foreign body is grasped, and extraction is accomplished gently, following the plane of orientation. This allows easier removal and helps avoid breaking the object into multiple foreign bodies.

When objects are deeply embedded, it may be better to leave them in place, rather than creating large surgical wounds to effect removal. Depending on foreign body location, operative intervention may be necessary for safe foreign body extraction.\textsuperscript{136}

After foreign body removal, tetanus prophylaxis and antibiotic coverage may be given when warranted by clinical circumstances. Patients with contaminated hand wounds and wooden splinters may be candidates for prophylaxis. Patients with suspected vascular or neurologic injuries require early evaluation, possibly but not invariably in the ED, by appropriate subspecialists. Some soft tissue foreign bodies may go undetected, leading to infectious sequelae. Careful discharge instructions and timely follow-up are crucial in these patients.
ANIMAL BITES

Perspective

Epidemiology

The incidence of animal bites has been difficult to determine because many are not reported. The Centers for Disease Control and Prevention (CDC) has provided the best epidemiological data available, but data sources are heterogeneous and have varied over time. In 1994, for example, based on a telephone survey, it was estimated that 756,000 people sought medical attention for dog bites. A CDC estimate for the year 2001, based on the National Electronic Injury Surveillance System—All Injury Program (NEISS-AIP), suggested that 368,000 people in the United States were treated in emergency departments (ED) during that year for dog bite-related injuries. The latter estimate of dog bite injuries is probably more accurate. Data from a surveillance network in Switzerland suggested that there were 190 dog bites per 100,000 persons in that country for the year 1995. By comparison, the U.S. numbers for 2001 of 133 per 100,000 fall somewhat below that range.

Estimates of bites from other species, including humans and cats, are far more difficult to estimate as the CDC groups these in a category with reptile and insect bites, as well as stings from coral, jellyfish, and plants.

Dog bites represent approximately 0.4% of all ED visits and account for 60 to 90% of bite injuries treated in the ED. Cat bites represent 1 to 15% of treated bites, rodents up to 7%, and other species (monkeys, ferrets, raccoons, foxes, livestock, bats, minks, kinkajous, other wild animals) less than 2% of bites.

Children are the most frequent victims of dog bites, and below the age of 15, males are bitten more often than females. For patients 15 or older, the difference in bite occurrence between the rate for males and females was not statistically significant. Most cat bites occur in or near the home of the victim. In the United States more than half of dog bites occur at home and about one third in a public place. Dog bite victims are more frequently female than male. In one study from Austria, approximately 82% of children sustaining dog bites were familiar with the dogs. This is not the case elsewhere. In Bangkok, for instance, dog bites are more likely to be inflicted by stray or “community” dogs and to occur in public places.

About 200 fatal attacks by dogs occur each decade in the United States. The majority of the victims are children younger than 10 years of age. The highest incidence has been reported in 1-year-old patients and decreases with increasing age. The breeds most frequently responsible are pit bulls, Rottweilers, and German shepherds. In at least half the cases, the attack involves an unrestrained dog on the owner’s property. For most of the fatalities in children younger than 1 year of age, the attack involved a pet dog and a child who was sleeping or in a crib.

Animal bites can usually be treated on an outpatient basis. Hospitalization is most often required for plastic surgery or repair of deep structures in fresh wounds, or for subsequent infection. Approximately 2% of victims who seek care for dog bites are hospitalized. Patients with dog bites are usually hospitalized at the time of the injury for operative repair, whereas most hospitalizations for cat bites are a result of infection that occurs several days after the initial bite.

PRINCIPLES OF DISEASE

Bites are traumatic injuries that can cause damage to skin, muscle, nerves, blood vessels, tendons, joints, and bones. Wounds may be lacerations, contusions, scratches, tears, or deep punctures. Contamination with oral flora from the biting animal makes local wound infection the principal treatment concern, and to a far lesser degree, the prospect of rabies or tetanus.

Dogs

Injury

The jaws of adult dogs can exert approximately 200 pounds per square inch (psi), enough to perforate sheet metal, but the teeth generally are not sharp. Most dog bites are large, relatively superficial crush injuries which damage skin and muscle but rarely reach tendon, bone, joint, or nerve. The wounds may be contusions with ecchymosis and hematoma, without any break in the skin, or large gaping wounds. Punctures occur less often. The large wound and emotional trauma of a dog bite typically precipitate an early visit for medical attention.

The lower extremities are most frequently injured in dog bites, but face, neck, and scalp wounds are common sites for dog bites in young children. In children up to 2 years old, dog bites can perforate the cranium, resulting in depressed skull fractures, brain laceration, intracranial abscess, and meningitis. Fractures of facial bones may also occur. In adults, dog bites rarely result in fracture, vascular injury, or tendon and nerve damage. However, bites from police dogs that are trained to hold their grasp until given the command to release
pose a significant risk of complications, in particular vascular injury. Infection, fracture, and nerve or tendon injury are also more common in bites from police dogs than those from civilian dogs.17

The overall incidence of infections from dog bites is 5 to 10%, only slightly higher than the 3 to 7% infection rate for nonbite lacerations sutured in the ED.18-20 However, dog bites on the hand have a higher risk of infection (12-30%). Dog bites of the face have a lower risk of infection (1-5%) than bites elsewhere.3,14,21-27 There is an obvious selection bias here, as the numbers refer to patients seen in the ED rather than all patients with dog bites, a good number of whom probably do not seek medical attention.

Bacteriology

More than 100 different organisms have been isolated from infected dog bites. Most infected wounds are polymicrobial.11,22,28,29 No one organism is responsible for more than 30% of infections.22,29 The organisms found in infected wounds are common mouth flora from the biting animal. Staphylococcus aureus, alpha-hemolytic and beta-hemolytic streptococci, Capnocytophaga canimorsus, Klebsiella, Bacillus subtilis, Pseudomonas, and Enterobacteriaceae are among the more frequently isolated aerobic organisms.28,30 NO-1, a gram-negative rod sensitive to β-lactams, quinolones, aminoglycosides, tetracycline, and sulfonamides, has recently been identified as a rare source of localized infection from dog and cat bites.31 Anaerobic organisms isolated from infections include Bacteroides, Fusobacterium, Peptostreptococcus, and other species. Anaerobic organisms are most often recovered along with aerobic species in cultures of infected wounds.28,30

Although much attention is focused on Pasteurella multocida, its role in causing infections in dog bites may be overestimated.22,23 P. multocida is found in the mouths of 77% of cats but in only 13% of dogs.31 Pasteurella species are isolated in 25 to 50% of infected dog bite wounds in some studies, although one study of infected dog bite found no Pasteurella.3,12,28,29 However, the Pasteurella species that have usually been isolated from dogs, such as Pasteurella stomatis, Pasteurella canis, and Pasteurella dagnatis, are less virulent varieties.28,33 When P. multocida is isolated from infected dog bites, it is frequently found in mixed culture with other organisms; when isolated from infected cat bites, P. multocida is often the sole pathogen.28

Capnocytophaga canimorsus. C. canimorsus, formerly known as dysgonic fermenter 2 (DF-2), is a fastidious gram-negative rod that can cause overwhelming sepsis. It is part of the normal oral flora of both dogs and cats. More than 100 cases have been documented since the organism’s discovery in 1976.24,25 About 90% of cases are attributed to contact with a dog, primarily through bites or scratches, but for approximately one quarter of infections, only dog contact (without a bite) was documented. A few infections have resulted from contact with cats. About 10% of cases are unrelated to any animal exposure. The disease tends to strike patients with alcoholic liver disease, functional or surgical asplenia, lung disease, or those taking corticosteroids. However, in 40% of victims, no underlying illness is identified.34,35

The disease begins within 2 to 3 days of exposure and is characterized by hypotension, disseminated intravascular coagulation (DIC), and renal failure. Purpura, particularly on the face, and petechiae are frequent findings and may progress to symmetrical peripheral gangrene.36 Cutaneous gangrene at the site of the bite strongly suggests C. canimorsus.40 Waterhouse-Friederichsen syndrome (adrenal hemorrhage with cutaneous ecchymoses) occurs, as well as metastatic infection, resulting in endocarditis, meningitis, peritonitis, and pneumonia. The mortality rate is 30%, with 70% of deaths occurring in immunocompromised patients.40

C. canimorsus grows slowly and requires special media and growth conditions. In the event of sepsis where contact with a dog or cat has occurred and this organism is suggested, the laboratory should be notified to prevent cultures from being misidentified or discarded prematurely. Although cultures may take up to 14 days, the organism can sometimes be identified in the patient’s blood smear at the time of presentation, or in blood culture media before macroscopic growth.38,40,41

Cats

Injury

The typical cat bite is a puncture wound caused by sharp teeth. Abrasions, lacerations, and avulsions may also result.42 Cats have long, slender, pointed teeth that can penetrate tendons, joints, and bone, inoculating bacteria deep into these tissues. The majority of these bites occur on the hand.3,42 Cat scratch injuries may also become infected, and when this occurs the same organisms are found due to the propensity of cats to lick their paws.

Wound Infection

The reported incidence of infection in cat bites is 30 to 50%, although this may be an overestimate since many patients present for treatment of cat bites only after an infection develops.3,5,42 In a prospective ED study of patients with cat bites, the overall infection rate was 16%, and most infections were present when the patient first sought care.42 Nevertheless, 24% of the infections required admission to the hospital. Cat bites have a substantially higher risk of infection than dog bites. The puncture wound itself is difficult to explore, irrigate, or débride. Location on the hand increases the risk of infection.

Pasteurella multocida. Another important factor in the development of wound infection after cat bites involves the presence of P. multocida, a highly virulent, gram-negative, facultatively anaerobic rod found in the oral cavity or nasopharynx of 70 to 90% of healthy cats.33 Wound infections and abscesses caused by P. multocida have occurred after cat scratches as well as bites and less often from dog bites or from open wounds that had been licked by dogs.42 P. multocida infections have also been reported after the bite of an opossum, rat, lion, rabbit, pig, wolf, monkey, and cougar.43,44

P. multocida wound infections appear to have a distinctly earlier onset, causing a rapidly progressive cellulitis that may be apparent within 6 hours and easily identifiable within 24 hours, whereas infections from other pathogens are usually not evident for 2 to 3 days. Presenting features include erythema, warmth, swelling, and tenderness. Purulent drainage, lymphangitis, and adenopathy may also occur. In addition to cellulitis, P. multocida can cause abscesses, tenosynovitis, joint infections, and osteomyelitis at the site of a bite and can seed arthritic joints and prosthetic valves, causing septic arthritis, endocarditis, and osteomyelitis at sites distant to the bite. Meningitis and pericarditis due to P. multocida after a bite have also been reported.40,47

In vitro, P. multocida is sensitive to penicillin, ampicillin, tetracycline, fluoroquinolones, amoxicillin-clavulanate, second- and third-generation cephalosporins, and trimethoprim-sulfamethoxazole (TMP-SMZ).33,47 The organism is resistant to vancomycin and clindamycin and shows borderline susceptibility to aminoglycosides. Oral first-generation cephalosporins may not be effective.48 Semisynthetic penicillins such as
oxacillin and dicloxacillin have been reported to have only minimal activity against *P. multocida* in vitro. Erythromycin is a relatively poor agent against *P. multocida*, but the extended-spectrum macrolide azithromycin shows good in vitro activity against this organism. However, the relevance of these in vitro data to wound care is occasionally unclear as culture-proven *P. multocida* infections have resolved after treatment with erythromycin, and oral cephalothin has been used to successfully treat a *P. multocida* infection that failed to respond to erythromycin.

### Rodents

Rodent bites result in small puncture wounds with a low risk of local wound infection. These bites are frequently seen in laboratory workers, in children in lower socioeconomic areas who are bitten while sleeping, and occasionally in pet owners. A number of diseases may be transmitted by rodent bites or scratches, including rat-bite fever, leptospirosis, tularemia, sporotrichosis, murine typhus, and plague, although nonbite contacts are the more common routes of transmission of systemic disease to humans. Rat-bite fever, caused by *Streptobacillus moniliformis* or *Spirillum minus* is rare, but can result from any rodent bite. It usually presents 1 to 3 days after the bite with abrupt onset of fever, chills, myalgias, and headache followed by a rash. Abscesses form in many tissues, including brain and myocardium and soft tissues. Involvement of joints occurs in 50% of patients, resulting in an asymmetrical migratory arthritis. Hantavirus pulmonary syndrome (HPS) is a rare febrile illness characterized by bilateral pulmonary infiltrates and respiratory decompensation resembling acute respiratory distress syndrome and is usually fatal. HPS is caused by viruses of the Hantavirus genus, for which rodents are the natural reservoir. Transmission usually occurs from the inhalation of aerosolized material but may occur from bites or direct contact.

### Primates

Monkey and other primate bites are said to have a high wound infection rate. The infecting organisms have not been well described, with the exception of one case of wound infection due to *Eikenella corrodens* and a case of osteomyelitis due to *P. multocida*. Old World macaque monkeys (Rhesus macaques, cynomolgus, and other Asiatic macaque monkeys) may harbor Cercopithecine herpesvirus 1, also called Herpesvirus simiae or more simply, B virus, which is fatal to humans if not treated early. Most victims of B virus infection in the United States were laboratory workers who were bitten or scratched by monkeys or who sustained scratches from cages; many of the exposures were considered trivial at the time. This virus has been found to be highly prevalent in adult macaque monkeys, making them unsuitable pets.

The disease in monkeys resembles that of human herpesviruses; monkeys may shed virus without symptoms but are more likely to shed when ill, under stress, immunocompromised, or breeding. Virus can be found in the conjunctiva, buccal mucosa, and genital areas, but most infected monkeys do not display any lesions. B virus can enter host cells within 5 minutes, making immediate wound care at the site of the most important step in prevention of transmission. Deep puncture wounds that are difficult to clean; inadequately cleansed wounds; and wounds of the face, neck, or thorax may pose greater risks of infection.

The incubation period is 2 days to 5 weeks, with most cases presenting within 5 to 21 days. The illness usually, but not always, is heralded by the appearance of vesicles at the site of the injury, sometimes associated with tingling, pain, or numbness. In some cases, the illness starts with peripheral or central nervous system symptoms, or it may begin as a flulike illness. Eventually, paresthesias at the site ascend along the infected extremity, and the victim develops headache, confusion, cranial nerve palsies, hemiparesis, and ultimately, coma and death. The case fatality rate is approximately 70%. Treatment is most successful if begun when vesicles first appear. With aggressive treatment, however, survival is possible even after central nervous system symptoms develop.

### Ferrets

The European ferret (*Mustela putorius furo*) is now the third most popular pet in the United States, with an estimated 5 to 7 million pet ferrets in 4 to 5 million households. The ferret is descended from the polecat, a member of the weasel, mink, and wolverine family. In the past, hunters bred ferrets to hunt rats and rabbits; they are extremely ferocious and tenacious with their prey. Although domesticated for more than 2000 years, the ferret appears to retain its instinctive propensity for attacking suckling animals and an attraction to the neck of its victim. Ferrets are known to attack infants and young children suddenly and without provocation, even in the presence of an adult. They usually attack around the face and neck, and often have to be pried off the victim. Extensive cosmetic repair after such attacks has been required.

Locking ferrets in a cage may not be an adequate safeguard; ferrets have been known to escape and hide for several days. Little is known about the bacteriology of ferret bites. Rabies, though uncommon, has been documented in ferrets, but there has not been a documented case of transmission to humans. In experimentally induced rabies, ferrets develop clinical signs (ataxia, paresis, anorexia, fever, hyperactivity) within 16 to 21 days after inoculation and secrete rabies in their saliva from 2 days before to 6 days after the onset of overt illness, which is similar to the way the illness behaves in other animals. The CDC recommends a management strategy of ferret bites similar to that for other domestic animal bites with regard to rabies, allowing a 10-day observation period after the bite, rather than immediate sacrifice and testing. A rabies vaccine for ferrets is available. Ferrets should be vaccinated at 3 months and yearly thereafter.

### Pigs

Pig bites are often deep, but may be deceptively small on the surface. They require careful exploration and débridement. Pathogens include *Pasteurella aerogenes*, *P. multocida*, *Escherichia coli*, *Bacteroides*, *Proteus*, and alpha-hemolytic and beta-hemolytic streptococci. Despite antibiotics and appropriate wound care, pig bites have a high risk of infection.

### Domestic Herbivores

The bites of horses result in severe soft tissue contusions, but virtually all heal uneventfully. Cattle do not have upper incisors, so they virtually never bite. Camels are well known for biting their handlers, particularly in the winter, reportedly in sudden vengeance for offenses committed previously. Unlike most other herbivores, the camel has canine teeth and can cause deep wounds, fractures, and amputations, most involving the handler’s upper limbs. These wounds are reported to have a very high rate of infection. Most domestic herbivores carry *Pasteurella multocida*. Because antibiotics are added to the feed of most domestic herbivores, bacterial isolates from these animals are frequently resistant to common antibiotics.
Wild Animals

Human encounters with large wild animals, such as wolves, coyotes, large cats, elephants, or bears, usually result in massive trauma and often death, from some combination of biting, swiping, throwing, goring, and trampling. Attacks by animals may result in major blunt or penetrating trauma, with major arterial blood loss, airway damage, intracranial and subarachnoid penetration, broken ribs and vertebrae, pneumothoraces, and intraperitoneal bleeding.16,69 Hyenas are known for their tremendously strong jaws and their frequency of attacks on humans in Africa. Hyenas target the face and can literally rip off a face or head with one clean massive bite. Bites of bears usually result in a series of punctures, with crushing and tearing of soft tissues, and underlying fractures, particularly of facial bones and those of the upper extremity. Big cats tend to go for the nape of the neck; their teeth may enter the pharynx, esophagus, and intervertebral space.69 A common killing mechanism is to shake the victim by the neck, which results in hyperextension injuries. The wounds grow rapidly and a higher morbidity than those in other areas of the body71-73 than wounds elsewhere on the body.71,72 Similarly, dog bites of the face and neck (including punctures) have an infection rate of only 0 to 5% even when sutured.21,22,27 Severe facial wounds that warrant hospital admission and operative repair have a substantially higher infection rate.

Delay in Care
The age of the wound may be one of the most important factors contributing to the risk of infection. In studies of nonbite wounds, delay in seeking care is associated with a higher risk of infection and complications.71,73 Dog bites in patients who delay care by 10 to 24 hours have a substantially increased risk of becoming infected.21,23 Time to presentation, presence of infection at presentation, and subsequent morbidity are strongly correlated in human bites of the hand.24,75

Host
Patients with underlying illnesses (e.g., diabetes, peripheral vascular disease) or those taking steroids are at decreased risk of becoming infected.71,72 Immunocompromised patients are probably at a higher risk for infection. Elderly patients in general have a higher risk of infection than other age groups for nonbite lacerations and dog bites.14,76

Approximately 150 systemic diseases of mammals can be transmitted by some route and in some form to humans. Leptospirosis, rat-bite fever, cat-scratch disease, tularemia, erysipelias, hepatitis B, bubonic plague, rabies, tetanus, and spottorchiocosis have all been transmitted through bites or scratches, but with the exceptions of rabies and tetanus, this mode of transmission is rare.79 Patients with these systemic illnesses present weeks or months after the exposure, so a history of animal contact must be elicited.

Systemic Infection

Infection Risk Factors

Location of Wound

In studies of nonbite lacerations, wounds on the hand and those below the knee have a greater propensity for infection and a higher morbidity than those in other areas of the body.71-73 (Table 58-1). The hand contains many poorly vascularized structures that do not resist infection well. The fascial spaces and tendon sheaths communicate, so an infection quickly spreads throughout the entire hand. For dog bites the infection rate of hand wounds is as high as 30%, regardless of suturing, whereas the infection rate of dog bites elsewhere averages only 9%.22,24,25 In a series studying cat bites, hand wounds had an infection rate of 19%; lower extremity wounds 20%; and arm, neck, or trunk wounds 5% or less.22 In contrast, nonbite lacerations of the head and neck have a lower risk of infection than wounds elsewhere on the body.71,72

First Aid and Wound Preparation

Animal bites should be treated as contusions, with immediate ice and elevation (Box 58-1). Direct pressure with a clean cloth or gauze for 10 minutes will stop most bleeding. Washing the wound with soap and water, ideally with a fine-pore sponge to minimize additional tissue trauma, substantially decreases the risk of rabies infection if done within 3 hours, so this should be carried out before the patient arrives at the hospital if possible.64

History

Practitioners should elicit the circumstances of the bite, the biting animal, and whether the animal is in captivity and has been immunized against rabies. Specific inquiry should be made about risks for poor wound healing (e.g., diabetes, peripheral vascular disease) and risks for increased susceptibility to C. canimorsus, specifically immune status, lung disease, steroid use, splenectomy, or alcoholism. Tetanus immunization status, allergies to medications, and availability and reliability of follow-up care should also be assessed.

Evaluation and Repair

Radiographs of the injured area may be indicated to detect possible fracture, foreign body, or joint penetration, although they are rarely necessary in dog bites in adults and older children. Infants and small children (up to 2 years old) who sustain substantial bite wounds to the scalp should have skull films or
well and sutured. It is probably safe to suture most uncomplicated dog bites. Lower extremity and hand wounds are at higher risk for infection and should be handled with extra caution (i.e., rarely sutured). Cat bites and primate bites on the face or scalp can be considered for suture repair, but sutures should be avoided in other locations. Puncture wounds from any species should not be closed. Contaminated wounds, wounds more than 12 hours old, or wounds infected at presentation should not be sutured. Most bite wounds that are going to be closed ought to have this done within 6 hours. Patients at risk for infection or poor wound healing should be treated conservatively, with sutures avoided in higher risk wounds. Proper alternatives include delayed primary closure or allowing healing by secondary intention. Patients and physicians may be reassured when small wounds are left open; a study comparing suturing with conservative treatment of uncomplicated, full-thickness hand wounds smaller than 2 cm demonstrated no difference in functional or cosmetic outcome. No current evidence shows that use of topical adhesive results in a lower infection rate than sutures.

A simple, sterile dry dressing is sufficient to protect the wound. Delayed primary closure requires that the wound be kept moist, usually with a wet saline dressing. Abrasions should be covered with a topical antibiotic and dry sterile dressing. Bites of the hands or over joints should be immobilized with a bulky soft dressing or a splint. Bite wounds are considered tetanus-prone (see Table 58-5). It is prudent to encourage patients to have wound checks within 1 to 3 days after the bite. Early follow-up is particularly important when the risk of a Pasteurella infection is high.

### Prophylactic Antibiotics

#### Dog Bites

Prophylactic antibiotics are not indicated for most routine dog bite wounds, except of the hand. Other high risk wounds (e.g., deep structure injury) and patients at high risk have traditionally been excluded from studies on prophylactic antibiotics and would probably benefit. Therefore a reasonable approach is to give prophylactic antibiotics to victims of...

CFI, closed-fist injury; TMP-SMX, trimethoprim-sulfamethoxazole.
*Includes levofloxacin, moxifloxacin, sparfloxacin. Quinolones not approved for children and pregnant women.
†Sulfonamides should not be given to pregnant women.
*Anaerobic coverage not necessary unless established infection; 50% of human mouth anaerobes resistant to penicillin.

Table 58-3

For prophylaxis, 5 days of an antibiotic that covers S. aureus and streptococcus is likely sufficient (Table 58-3).

On the other hand, for treatment of established dog bite infection, coverage of P. multocida should be included. A second- or third-generation cephalosporin or amoxicillin-clavulanate are all excellent first-line agents. For the adult allergic to penicillin, a combination of clindamycin plus sulfamethoxazole can be used. Doxycycline and fluoroquinolones are also effective but should not be used in children. For penicillin-allergic children, clindamycin plus trimethoprim-sulfamethoxazole (TMP-SMX) is acceptable.

**Capnocytophaga canimorsus.** There are no studies on prevention of C. canimorsus infection, but it is prudent to give patients with known risks prophylactic antibiotics after a dog or cat bite. It would be logical to include in this population immunocompromised patients, including those with diabetes. In vitro, C. canimorsus is susceptible to penicillin G, ampicillin, carbenicillin, cephalexin, ceftizoxime, clindamycin, erythromycin, tetracycline, fluoroquinolones, vancomycin, and chloramphenicol, although one clinical case of resistance to penicillin, erythromycin and clindamycin has occurred. C. canimorsus displays variable susceptibility to TMP-SMX, and it appears to be resistant to all aminoglycosides. For prophylaxis, consider amoxicillin/clavulanate or penicillin for 5 days. For treatment of established infection, an intravenous second- or third-generation cephalosporin, amoxicillin/sulbactam or clindamycin plus a fluoroquinolone (in adults) are acceptable (see Table 58-3).

**Cat Bites**

One small controlled study on the use of prophylactic antibiotics in cat bites has been published, demonstrating reduced infection with prophylaxis. No other randomized studies on cat bites have been conducted. A Cochrane review, however, concluded that there was no evidence that the use of prophylactic antibiotics are effective for cat bites, although it did conclude that animal bites on the hands benefit from prophylaxis. Because cat bites have been reported to have a high likelihood of infection and infected cat bites often require hospitalization, it may be prudent to consider prophylactic antibiotics for cat bites in certain circumstances such as hand wounds, but sufficient data on this question is lacking.

*P. multocida* should be specifically covered if prophylaxis is given, as well as S. aureus and Streptococcus species. P. multocida may be resistant to semisynthetic penicillins (dicloxacillin, methicillin) as well as erythromycin, clindamycin, first-generation cephalosporins, and aminoglycosides. These antibiotics should not be used to treat *Pasteurella* soft tissue infections and should be avoided in terms of prophylaxis considerations. *Pasteurella* is usually sensitive to penicillin, although some β-lactamase-producing strains have been recovered. *Pasteurella* is also usually sensitive to ampicillin, ticarcillin, amoxicillin-clavulanic acid, tetracyclines, second- and third-generation cephalosporins, fluoroquinolones, and TMP-SMZ. For prophylaxis, excellent coverage and convenience are afforded by a second-generation cephalosporin such as cefuroxime, which needs to be taken only twice a day. Amoxicillin-clavulanate is also a good choice, although it requires more frequent dosing and has substantial side effects.

Extended-spectrum fluoroquinolones cover *P. multocida* and have good staphylococcal and streptococcal coverage. Given the many other alternatives for prophylaxis, however, the use of fluoroquinolones as first-line agents is not recommended because of cost, lack of clinical experience, and concerns that overuse will result in resistance. Additionally, these drugs are not approved for children or pregnant women.

TMP-SMX offers reasonable coverage against *P. multocida* as well as staphylococci and streptococci and is a low-cost, although not ideal, alternative (see Table 58-3). Tetracycline is not advisable for *P. multocida* coverage because it achieves low tissue levels at a very slow rate and is not very effective against common bite pathogens, including streptococci, staphylococci, diphtheroids, *Bacteroides* and anaerobic gram-positive cocci. When used together, however, tetracycline and erythromycin have a synergistic effect against *Pasteurella.*

For very high risk bites, such as cat bites on the hands, patients should receive an antibiotic in the ED. Intravenous (IV) treatment is preferable because it achieves detectable levels in the wound much sooner than by the oral (PO) or intramuscular (IM) route. However, even a PO dose of antibiotic at the time of treatment is preferable to giving patients a prescription that may not be filled for 24 hours. The usual course for prophylaxis is 5 days.

**Other Animal Bites**

Patients who sustain pig bites or camel bites, especially on the hand, should receive antibiotic prophylaxis. Prophylaxis should include coverage against *Pasteurella.* Rodent bites and most
other species have a lower risk of wound infection, so prophylaxis generally is not indicated.

**Monkey Bites**

Monkey bites are considered to have a high risk for bacterial infection. Although there are no data on the use of prophylactic antibiotics, antibiotics are advisable for full-thickness bites, particularly those on the hand. Management of these wounds involves selection of antibiotics to cover the most common pathogens for animal bites, *Staphylococcus aureus*, anaerobic cocci, and *Bacteroides*. A good choice would be amoxicillin and clavulanic acid (875/125 mg PO bid for 5 days). An acceptable alternative is ciprofloxacin (500 mg PO bid for 5 days) plus metronidazole (500 mg PO tid for 5 days).

Prevention of B virus infection requires *rapid* local wound care; this should be performed at the scene of the exposure before medical evaluation is sought. The wound should be washed with povidone-iodine, chlorhexidine, or a detergent soap solution for at least 15 minutes; eyes or mucous membranes should be irrigated with sterile saline or running water for at least 15 minutes. It is recommended that workers with potential exposures be referred by their occupational health care provider to a person knowledgeable about B virus, as treatment decisions are complex; however, most laboratories provide workers with written information and appropriate kits for specimen collection if they are referred to an ED.

Clinicians examining patients with fresh monkey bites from macaque monkeys, in particular Rhesus and cynomolgus, should determine the risk of exposure by evaluating the time, source, location, and type of exposure, as well as the timeliness and adequacy of cleansing and examination of the wound. Cleansing should be repeated. The health status of the monkey should be determined, and if it can be done safely, the facility should examine the monkey for active lesions. Cultures of bite or scratch wounds or splashes should never be done prior to cleansing but are often negative after cleansing. However, a positive culture for B virus would prompt prophylaxis if not previously given. Prophylaxis with antiviral therapy is recommended only where the risk of transmission is high (Table 58-4) because human cases of infection are extremely rare, despite thousands of potential exposures each year and treatment may interfere with seroconversion, confounding diagnostic testing. The recommended therapy is valacyclovir, (1 g PO q8 for 14 days) or alternatively, acyclovir (800 mg PO 5 times daily for 14 days). Prophylaxis, when indicated, can be given up to 5 days after the exposure. Patients should be counseled about the signs and symptoms of B virus infection and told to immediately seek care if any occur. Patients with high risk exposures should be told to avoid activities that involve exchange of bodily fluids, including saliva. Close follow-up for the next 4 weeks is essential.

**DISPOSITION**

Patients with life-threatening or limb-threatening injuries or with severe cosmetic defects requiring operative repair, particularly children, should be admitted to the hospital. Most other patients may be discharged with close follow-up. Many U.S. cities and counties have animal bite-reporting laws. These require the ED to obtain details on the biting incident, the animals involved, and names of owners and submit a report shortly after the victim is treated. Public health officials may be able to locate escaped animals or those that are potentially ill based on these reports, as well as to provide consultation regarding the need for rabies prophylaxis and animal management.

**Monkey Bites**

**Prophylaxis Considered**

- Mucosal splash that has been adequately cleaned
- Laceration (with loss of skin integrity) that has been adequately cleaned
- Needlestick involving blood from an ill or immunocompromised macaque
- Puncture or laceration occurring after exposure to either objects contaminated with body fluid (other than from a lesion) or potentially infected cell culture

**Prophylaxis Not Recommended**

Skin exposure in which the skin remains intact
Exposure associated with nonmacaque species of nonhuman primates

### Treatment of Infected Bites

Patients who present or return with infected bites should be assessed for complications such as retained foreign body, tenosynovitis, joint infection, or fracture. Abscesses should be drained. Patients with wound infection and fever, systemic symptoms, lymphangitis, or deep structure involvement should be hospitalized for administration of IV antibiotics and surgical consultation as needed. In addition, high risk patients (e.g., diabetic, immunosuppressed, elderly) with localized infections, those with peripheral vascular disease, and those likely to be noncompliant with therapy require hospitalization, although IV antibiotic treatment in a short-stay unit or at home with a visiting nurse may be a suitable alternative. Empiric, broad-spectrum antibiotic coverage should be started and the affected area elevated and immobilized. Anaerobic coverage, should be included for infected bite wounds. Wound or blood cultures are usually not necessary unless the patient fails to respond to the first line of therapy. Healthy patients with localized infections may be treated with oral antibiotics at home with close follow-up. The infected area should be immobilized with a splint; the patient should be instructed in strict elevation of the infected area and assessed daily until the infection has resolved.

### HUMAN BITES

**PERSPECTIVE**

**Epidemiology**

Human bites of the hand, especially the clenched-fist or closed-fist injury (CFI), or fight bite, are associated with a high incidence of infectious complications. These include septic
arthritis, tenosynovitis, and osteomyelitis, as well as surgical amputation necessitated by infection. Most simple human bites elsewhere on the body are probably no more significant than ordinary lacerations. The reported rate of infectious complications in human bites of the hand is 25 to 50%. The majority of infections already exist when the patient first presents for care. The high infection rate results from a combination of factors: the location on the hand, the position of the hand at the time of injury, the mechanism of entry, associated injuries, the bacteriology of the human mouth, and a delay in seeking care.

## PRINCIPLES OF DISEASE

### Fight Bites

The CFI is a ragged laceration most often found over the metacarpophalangeal joints of the middle finger and ring finger. It results when an individual strikes another person’s mouth with a closed fist. Associated traumatic injuries include the boxer’s fracture (distal ring or small finger metacarpal fractures), amputations, foreign bodies, and extensor tendon lacerations. Penetration of the joint occurs in up to 62% of wounds; up to 58% involve injury to the bone. The presence of an extensor tendon laceration is highly predictive of joint penetration. Patients who have deep structure involvement have significantly more morbidity than those who do not. Another type of fight bite is an actual bite, usually on the finger, which may penetrate the proximal or distal interphalangeal joint; this can result in a traumatic amputation.

### Bacteriology

Information on the bacteriology of human bites comes almost exclusively from hand bites, with the vast majority of these being CFIs. Infected wounds are polymicrobial. *Streptococcus* species and *Staphylococcus aureus* are the most common aerobic pathogens. Gram-negative rods and anaerobes are more frequently isolated from infected human bites than other types of hand infections, including those from animal bites. The presence of anaerobes in mixed infection may be associated with a worse outcome. *Eikenella corrodens*, a facultatively anaerobic gram-negative rod harbored in human dental plaque, is found in 25 to 29% of CFI infections. It acts synergistically with aerobic organisms, most frequently *streptococci*, and is thought to account for greater morbidity in these wounds. *E. corrodens* is susceptible to penicillin, ampicillin, second- and third-generation cephalosporins, carbenicillin, tetracycline, and the fluoroquinolones. Resistance to penicillin has been reported. *E. corrodens* is resistant to penicillinase-resistant penicillins, methicillin, nafcillin, aminoglycosides, clindamycin, vancomycin, and metronidazole.

Susceptibility to first-generation cephalosporins and erythromycin is suboptimal.

### Other Human Bites

Human bites in locations other than the hand have about the same rate of infection as ordinary lacerations, if proper local wound care is administered. Human bites of the face have about a 2.5% infection rate.

In children, approximately 70% of human bites are abrasions, which generally do not become infected. The reported infection rate of human bites in children is 9 to 12%. Most of these infections are already established at the time of the initial visit, usually in patients who have delayed care for more than 12 to 18 hours.

Wounds from the victim’s own teeth, usually a result from a fall or a seizure, may be considered bites. Wounds that only involve the mucosa or tongue have a low infection rate, from 0 to 12%. Mucocutaneous (through-and-through) lacerations have an infection rate of up to 30% in the absence of prophylactic antibiotics. Organisms cultured from these infected wounds include *Streptococcus*, *Staphylococcus aureus*, *Epidermidis*, *Bacteroides*, *Corynebacterium*, *Neisseria*, and *Haemophilus haemolyticus*. **Transmission of Disease**

Human bites have resulted in the transmission of actinomycosis, syphilis, tuberculosis, herpes, hepatitis C, and hepatitis B. *Herpes simplex* virus is a well-known occupational hazard for nurses, physicians, dentists, and oral hygienists. Although HIV is secreted at some time in the saliva of up to 44% of infected patients, the CDC does not consider human bites to carry a risk of transmission unless there is exposure to blood in the process. HIV is not often present in the saliva of most infected patients, and when it is, the titer of virus is very low. Cases in which HIV has convincingly been transmitted through a bite involved significant amounts of blood mixed with the saliva. Nevertheless, when a significant bite has occurred, and particularly if the biter is known to be HIV-positive, it is reasonable to consult with infection control experts locally or at the CDC. The potential risk of HIV transmission to the person inflicting the bite should also be considered.

### MANAGEMENT

The approach to the human bite depends on the location and the mechanism of injury. Any laceration or puncture in the vicinity of the metacarpophalangeal joint should be considered a CFI unless proved otherwise. Full-thickness bites on the hand should be considered high risk. Hand radiographs should be obtained, looking for fractures, dislocations, retained tooth fragments or other foreign bodies, or air in the joint space. A “skyline” view, but not standard finger views, may demonstrate vertical articular fractures of the metacarpals.

A wound should be assessed for signs of established infection and a careful neurovascular examination performed, paying particular attention to the extensor function. The wound should then be anesthetized and explored in a bloodless field to look for foreign bodies, tendon laceration, or joint penetration. It is essential that the wound be examined through the full range of motion, including the position at the moment of injury. The wound should be irrigated and débrided. Wounds that demonstrate tendon lacerations should be presumed to have joint involvement as well, and this finding should prompt consultation by a hand surgeon.

Although there are no controlled studies on suturing human bites, the high rate of infection and complications of human bites on the hand suggest that they should be left open rather than sutured. The wound should be covered with a dry sterile dressing and the hand splinted in a position of function either with a plaster splint or by packing the palm with bulky gauze and wrapping the hand in a mitten-type dressing. Human bites are considered to be tetanus-prone wounds (Table 58-5).
aggressive débridement, and suturing if anatomy permits and cosmetic considerations are important. 105

Antiviral Agents

Victims of bites from persons potentially infected with HIV or hepatitis should receive exceptionally rapid, vigorous, and thorough wound cleansing with soap and water, to remove saliva, followed by irrigation with virucidal agents such as 1% povidone-iodine. A baseline HIV blood test and hepatitis antibodies at the time of injury should be obtained or arranged, along with a follow-up test in 6 months. If the bite involved blood, hepatitis B and HIV prophylaxis may be warranted. Consultation with the CDC’s postexposure prophylaxis hotline regarding possible blood-borne exposures is available 24 hours a day (1-888-448-4911; http://www.ucsf.edu/hivcntr/).

Prophylactic Antibiotics

Antibiotic prophylaxis is recommended for full-thickness human bite wounds of the hand (see Tables 58-2 and 58-3). One randomized, placebo-controlled study of hospitalized patients with uninfected human bites on the hand found no infections in patients who received antibiotics, whereas those who received placebo had a 47% infection rate. 78 Although good results have been achieved historically in selected situations without prophylactic antibiotics when patients presented early and received appropriate wound cleansing, this is probably not optimum management today. 72,73 Antibiotics are also indicated for high risk wounds elsewhere on the body, including deep punctures, severe crush injuries, contaminated wounds, older wounds, and wounds in patients with underlying illnesses. The antibiotic selected should offer coverage for gram-positive organisms and E. corrodens, such as with a second-generation cephalosporin or amoxicillin-clavulanate, and should be given for 5 days.

Mucosal lacerations from a person’s own teeth, including those of the tongue, should be irrigated well. Suturing is advisable only for deeper and larger wounds. Although such wounds may have a higher risk of infection, prophylactic antibiotics do not necessarily reduce the incidence. 95 Through-and-through lacerations, from a tooth puncture through the skin of the lower lip, may require a layered closure and are at high risk for infection. Prophylactic antibiotics probably reduce the risk. 95 Penicillin for 5 days remains the regimen of choice.

Infected Wounds

Infected human bites of the hand require both aerobic and anaerobic cultures, and the patient should be treated with IV antibiotics that cover gram-positive organisms, E. corrodens, and anaerobes. Anaerobes isolated from human bite wounds produce β-lactamase and are often resistant to penicillin. Treatment options include amoxicillin-sulbactam, cefoxitin, and ticarcillin-clavulanate. Penicillin-allergic patients may receive clindamycin plus TMP-SMX or clindamycin plus a fluoroquinolone, although data for these regimens are limited.

DISPOSITION

Patients with Infection

All patients with infected human bites of the hand should be hospitalized (Box 58-2). Localized infections of human bites not on the hand can usually be treated without hospitalization in immunocompetent patients with no evidence of lymphangitis or systemic symptoms for whom appropriate follow-up can be arranged.

Patients without Infection

Reliable, otherwise healthy patients who present within 24 hours without infection and have no tendon, joint, or bone damage may be treated at home with close follow-up, preferably within 1 or 2 days. 74,75 Discharge instructions should include immobilization, elevation, and sterile dressing changes every 6 hours.

Patients at high risk, such as those with delayed presentation or deep structure involvement, require prophylactic parenteral antibiotics and close evaluation. Consultation with a hand surgeon is highly recommended, and hospitalization is generally prudent. Although many human bites are a consequence of mutual aggression, the physician must keep in mind that the patient may be the victim (or perpetrator) of child, spousal, or elder abuse. 98 All states require reporting of suspected child abuse; laws vary for spousal or elder abuse. In all cases, details of the incident should be documented and the wound carefully described in the record. Counseling or referral should be offered when appropriate.

PERSPECTIVE

Epidemiology

Venomous animals account for considerable morbidity and mortality worldwide. Snakes alone are estimated to inflict 2.5 million venomous bites annually, with approximately 125,000 deaths. The actual numbers may be much larger. Southeast Asia, India, Brazil, and areas of Africa lead the world in snakebite mortality. It is impossible to estimate the worldwide morbidity and mortality resulting from other venomous animals such as bees, wasps, ants, and spiders.

Approximately 45,000 snakebites occur annually in the United States; 7000 to 8000 are inflicted by venomous snakes, and 5 to 10 result in death. Table 59-1 categorizes fatalities caused by venomous animals in the United States for the 20-year period from 1950 to 1969. Insects were responsible for 52%, snakes for 30%, and spiders for 13%. Specifically, bees were responsible for the most fatalities, followed by rattlesnakes, wasps, and spiders. Historically, most of the recorded spider deaths were caused by the black widow, although the brown recluse spider has been implicated in an increasing number of deaths.

The American Association of Poison Control Centers began collecting data in 1983 on deaths caused by venomous animals. Their 20-year experience shows a significant number of exposures by bite or sting but relatively few deaths (Table 59-2). Although these data include most of the United States, there is no requirement that hospitals, emergency departments, coroners, or public health agencies report deaths or exposure to Regional Drug and Poison Information Centers. This decline may be caused by an actual decrease in mortality or may be due to inadequate reporting. Meaningful morbidity data, such as the number of amputations, hospitalizations, and disabilities, do not exist. The number of exposures and deaths from exotic snakes seems to be increasing, possibly because of interest in collecting so-called hot or venomous varieties such as cobras, mambas, and vipers. The morbidity from marine animal injuries is increasing in proportion to the number of people exposed to the ocean and the number of private collectors, but the mortality has not increased dramatically. An increase in outdoor recreational activities such as camping, scuba diving, and wilderness trekking puts more people in proximity to venomous animals and increases the risk of envenomation. Most exposures occur from April to October, when animals are most active and potential victims are outdoors and involved in activities that might increase their risk for envenomation. Of course, many spider bites and exotic animal envenomations that occur indoors can take place at any time. Most deaths seem to occur in very young, elderly, and/or inappropriately treated patients.

Venom Delivery

Animals that have developed specific venom glands and venom delivery systems can be found in every class, including, most recently, birds. The toxin and toxic apparatus vary from class to class. For example, the rattlesnake has modified salivary glands and maxillary teeth and uses this system primarily to obtain food. The bee has a modified ovipositor that is used mainly for defense. Poisonous and venomous animals are not the same and should be differentiated. Animals can be considered poisonous because of various toxins distributed in their tissues. For example, certain shellfish, toads, and barracuda have been known to cause death after ingestion. However, only animals with specific glands for producing venom connected to an apparatus for delivering that venom to another animal can be considered venomous.

Most venomous animal injuries seen in the emergency department are minor problems, but some injuries must be given priority. Venomous snakebites, black widow spider bites, certain marine animal envenomations, and anaphylactic reactions to insect stings are life-threatening emergencies requiring immediate attention.

VENOMOUS REPTILES

Snakes

Snakes first appeared in the late Cretaceous period, and venomous snakes evolved approximately 50 million years later in the Miocene epoch. Of the 3000 species of snakes, approximately 10 to 15% are venomous. Of the 14 families of snakes, 5 contain venomous species. Snakes are distributed throughout most of the earth’s surface, including fresh and salt water. The major exceptions are the Arctic and Antarctic zones, New Zealand, Malagasy, and many small islands. Most snakebites occur in tropical and subtropical climates, especially in agricultural settings where the inhabitants go barefoot. Sea snakes are found only in the Pacific and Indian Oceans. Snakes are
Venomous snakes, States having the highest death rates are North Carolina, Arkansas, Texas, and Georgia. The anatomic distribution of snakebites is not surprising. Of all snakebites, 97% occur on the extremities, with two thirds on the upper extremities and one third on the lower extremities. This is a reversal of the previous trend and may reflect bites being provoked rather than accidental. Bites that occur accidentally are considered “legitimate,” whereas bites that occur when attempting to handle or disturb a snake are considered “illegitimate.” Men are bitten nine times more frequently than women.

Imported venomous snakes have recently been an increasing problem throughout the United States. In the past, only zoos, research centers, and herpetologists kept exotic venomous snakes. Today, however, hundreds of people are raising deadly venomous snakes without the necessary precautions, such as specialized cages, safe handling techniques, and rapid access to specific antivenin. They place not only themselves in danger but also their families and the general public.

Classification and Characteristics

The five venomous families of snakes are the Colubridae, Hydrophiidae, Elapidae, Viperidae, and Crotalidae. The Colubridae, although representing 70% of all species of snakes, have very few venomous members dangerous to humans; these include the boas and bird snake. The Hydrophiidae are sea snakes. The Elapidae are more common and include the cobras, kraits, mambas, and coral snakes. The Viperidae, or true vipers, are represented by Russell’s viper, the puff adder, the Gaboon viper, the saw-scaled viper, and the European viper. The Crotalidae, or pit vipers, are sometimes considered a separate family and sometimes a subfamily of the Viperidae. Among the pit vipers are the most common American venomous snakes, such as rattlesnakes, water moccasins, copperheads, the bushmaster, and the fer-de-lance. Several species of Asian pit vipers are responsible for bites in Okinawa and bites by imported snakes in the United States.

Pit vipers, the most prevalent venomous snakes in the United States, are native to every state except Maine, Alaska, and Hawaii. They are classified into three main groups: true rattlesnakes (genus *Crotalus*), copperheads and water moccasins (genus *Agkistrodon*), and pygmy or Massasauga rattlesnakes (genus *Sistrurus*). Pit vipers account for 98% of all venomous snakebites in the United States.

The Colubridae and Hydrophiidae families have few venomous members and are responsible for even fewer injuries. Some colubrid species found in the United States that were previously thought to be harmless may indeed be venomous. Examples are the Lyre snake and the wandering garter snake. No deaths have been reported, but the problem has generated much interest among herpetologists and toxicologists. The yellow-bellied sea snake (*Pelamis platurus*; family Hydrophiidae) has been found off the coast of southern California and western Mexico, but bites by this snake are rare.

The other major group of venomous snakes in the United States is the coral snakes. The eastern coral snake (*Micruroides fulvius*) is found in North Carolina, South Carolina, Florida, Louisiana, Mississippi, Georgia, and Texas. The western or Sonoran (*Micruroides euryxanthus*) coral snake is native to Arizona and New Mexico. Although both species are generally quite shy unless handled, the eastern coral snake is considered deadly. There are no records of fatalities caused by the western species.

Coral snakes can be readily identified by their color pattern. At first glance, they resemble one of several varieties of king

**Table 59-2** Venomous Animal Injuries and Deaths, 1983–2006

**Epidemiology**

The incidence of reported venomous snakebites is greatest in the southern United States, which has the largest number of poikilotherms, which accounts for their distribution and activity. Their inability to raise their body temperature above ambient levels restricts their activity to a fairly narrow temperature range, approximately 25°C to 35°C. All snakes are carnivorous, and their venom apparatus evolved for the purpose of obtaining food.

**Classification and Characteristics**

The five venomous families of snakes are the Colubridae, Hydrophiidae, Elapidae, Viperidae, and Crotalidae. The Colubridae, although representing 70% of all species of snakes, have very few venomous members dangerous to humans; these include the boas and bird snake. The Hydrophiidae are sea snakes. The Elapidae are more common and include the cobras, kraits, mambas, and coral snakes. The Viperidae, or true vipers, are represented by Russell’s viper, the puff adder, the Gaboon viper, the saw-scaled viper, and the European viper. The Crotalidae, or pit vipers, are sometimes considered a separate family and sometimes a subfamily of the Viperidae. Among the pit vipers are the most common American venomous snakes, such as rattlesnakes, water moccasins, copperheads, the bushmaster, and the fer-de-lance. Several species of Asian pit vipers are responsible for bites in Okinawa and bites by imported snakes in the United States.
snake found in the southern United States. The coral snake can be differentiated from the king snake by two characteristics: The nose of the coral snake is black, and the red and yellow bands are adjacent on the coral snake but separated by a black band on the king snake. The popular rhyme is as follows:

Red next to yellow, kill a fellow.
Red next to black, venom lack.

This rhyme can be used only in the United States; Brazilian coral snakes have red next to black bands, and some coral snakes have no red bands.

Identification

In the identification of venomous snakes, two principles should be kept in mind: Only experts should handle live snakes, and even dead snakes can envenom careless handlers. It is not difficult to differentiate between pit vipers and harmless snakes found in the United States (Fig. 59-1). Pit vipers, as their name implies, have a characteristic pit midway between the eye and the nostril on both sides of the head. This pit is a heat-sensitive organ that enables the snake to locate warm-blooded prey. Pit vipers may be identified through other methods, but this characteristic is 100% consistent. The triangular shape of the head, the presence of an elliptic pupil, the arrangement of subcaudal plates, the tail structure, and the presence of fangs are useful characteristics but are inconsistent. An individual specimen may not fit the classic description, depending on the age of the snake, the time of the year, and the condition of the tail and mouthparts. A person should never attempt to identify pit vipers by color or skin patterns (Fig. 59-2).13,14

Size is not an important factor in identifying various reptiles. Venomous snakes range in length from several inches to several feet. Although a 6-foot eastern diamondback rattlesnake is much more dangerous than a 10-inch copperhead, all venomous snakes are able to envenom from birth and should be treated as though they are dangerous.

Exotic snakes that are not pit vipers are not as easily identified. If possible, they should be safely transported to an expert for positive identification. Local zoos, herpetology groups, and colleges often have individuals who can identify unknown snakes. Usually, however, a person bitten by an exotic snake knows the type of snake or at least the common name of the snake.

Other Reptiles

Only two venomous lizards are found in the world, both in the southwestern United States and Mexico. They are the Gila monster (Heloderma suspectum) and the Mexican beaded lizard (Heloderma horridum). Fortunately, both these lizards are non-aggressive and rarely encountered. Bites usually result from handling the animals in captivity. The Gila monster and the Mexican beaded lizard are easily identifiable. Both have thick bodies, beaded scales, and either white and black or pink and black coloration.

Principles of Disease

Toxins

The two main factors influencing the pathophysiology of any venomous animal injury are the toxic properties of the venom and the victim’s response to these toxins. In the past, snake venoms were classified as either neurotoxic or hematotoxic, depending on the observed response of the victim to the various venoms. Modern toxicologic investigation has shown that this classification is inadequate because most snake venoms studied contain compounds that have many toxic properties. It is true, however, that the venom of a particular species of snake may show a clinical response, predominantly neurotoxic or hematotoxic.

![Figure 59-1. Identification of venomous and nonvenomous snakes.](image)

![Figure 59-2. Western diamondback rattlesnake (Crotalus atrox).](image)
The toxic components of snake venom can be classified into four broad categories: enzymes, polypeptides, glycoproteins, and low-molecular-weight compounds. They can also be classified as protein and nonprotein compounds. Proteins, which account for most of the toxic manifestations, make up 90 to 95% of venom. Symptoms can generally be classified as local or systemic. Local effects are usually caused by enzymatic action on the various cellular and noncellular structures in the victim’s tissues. These enzymes can cause coagulation, anticoagulation, cell lysis, hemorrhage, hemolysis, and the destruction of nucleic acid, mitochondria, and other organelles.

Polypeptides are structurally smaller and more rapidly absorbed than proteins and may account for the venom’s effects on presynaptic and postsynaptic membranes and other organ systems.

Phospholipase A can inhibit electron transfer at the level of cytochrome c and render mitochondrial-bound enzymes soluble. It can hydrolyze phospholipids in nerve axons, break down acetylcholine vesicles at the myoneural junction, cause myonecrosis, and induce lysis of red cell membranes. This single enzyme has been identified in all venoms of Hydrophiidae, Elapidae, Viperidae, and Crotalidae thus far investigated.

Elapidae and Hydrophiidae venoms have predominantly systemic effects, whereas Colubridae, Viperidae, and Crotalidae venoms have mainly local effects. There are many exceptions to this general division. For example, the venom of the Mojave rattlesnake (Crotalus scutulatus) may show minimal local effects and significant systemic effects, whereas the venom of the cobra (Naja naja) may cause extensive local tissue destruction.

Venom Delivery

The mechanism for delivering venom is fairly standard among snakes. It consists of two venom glands, hollow or grooved fangs, and ducts connecting the glands to the fangs. The glands, which evolved from salivary glands, are located on each side of the head above the maxillae and behind the eyes. Each gland has an individual muscle and a separate nerve supply that allow the snake to vary the amount of venom injected. The venom duct leads from the anterior portion of the gland along the maxilla to the fangs. Pit vipers have fangs that are large anterior maxillary teeth. These teeth are hollow and rotate outward from a resting position to a striking position. The coral snake has fixed, hollow maxillary teeth that are much smaller than those of pit vipers. The fangs in most snakes are shed and replaced regularly, and it is not unusual to see a snake with fixed fangs on one or both sides of its mouth.

The snake can control the amount of venom injected. In biting a human, a prey much too large to swallow, the snake may become confused or disoriented, especially if injured or surprised, and inject little or no venom (a “dry” bite). However, the snake may inject more than 90% of the contents of the gland for the same reasons.

Clinical Features

The signs and symptoms of a venomous snakebite vary considerably and depend on many factors. From 30 to 50% of venomous snakebites result in little or no envenomation. A person with impaired cardiovascular, renal, or pulmonary function is less able to cope with even moderately severe envenomation. Because of these multiple variables, the individual clinical response is the only way to judge the severity of a venomous snakebite. Factors that influence the effects of a snakebite are the age, health, and size of the snake; the relative toxicity of the venom; the condition of the fangs; whether the snake has recently fed or is injured; the size, age, and medical problems of the victim; and the anatomic location of the bite.

Local envenomation, if left untreated, can cause serious systemic problems (e.g., disseminated intravascular coagulation, pulmonary edema, and shock) as the toxic products are absorbed. The victim’s autopharmacologic response to the envenomation must also be taken into account. An IgE-mediated anaphylactic-type reaction may develop in victims of a previous snakebite when re-exposed to the venom. Many venoms contain enzymes that trigger the release of bradykinin, histamine, and serotonin from the patient’s cells, which may cause fatal anaphylactic reactions. A wave of effects ranging from minimal pain to multisystem failure and death can occur over a period of several days.

Pit Vipers

The most consistent symptom associated with pit viper bites is immediate burning pain in the area of the bite, whereas pain may be minimal with bites of Elapidae and other exotic snakes. With pit vipers, the severity of pain is probably related to the amount of venom injected or the degree of swelling. Edema surrounding the bite that gradually spreads proximally is a common finding. This edema is usually subcutaneous, begins early, and may involve the entire extremity. Compartment syndrome has been described; however, it is unusual even with severe edema. It has been reported more frequently in models involving intracompartmental venom injection.

Most fangs do not penetrate into the fascial compartments, although muscle destruction may result from direct toxicity. Mortality is less frequent with distal bites to the toe and finger and is greatly increased with intravenous bites. An intravenous bite from any venomous snake is likely to be fatal. Petechiae, ecchymosis, and serous or hemorrhagic bullae are other local signs. Necrosis of skin and subcutaneous tissue is noted later and may result from inadequate doses of antivenin. Many systemic symptoms, such as weakness, nausea, fever, vomiting, sweating, numbness and tingling around the mouth, metallic taste in the mouth, muscle fasciculations, and hypotension, often occur after pit viper envenomation.

Death from pit viper bites is associated with disruption of the coagulation mechanism and increased capillary membrane permeability. Ultimately, these two processes lead to massive pulmonary edema, shock, and death. Heart and kidney damage occurs secondary to these mechanisms. Specific toxins in certain species may act directly on specific organs, such as the heart or skeletal muscle. An allergic type of reaction may add to this process through release of histamine and bradykinin.

Coral Snakes

Signs and symptoms can vary considerably with bites of coral snakes, Mojave rattlesnakes, and many exotic snakes, especially cobras and Australian elapids. Little pain and swelling may occur. Many of these species’ venoms contain compounds that block neuromuscular transmission at acetylcholine receptor sites and have direct inhibitory effects on cardiac and skeletal muscle. Ptosis is common and often the first outward sign of envenomation. Other signs and symptoms include vertigo, paresthesia, fasciculations, slurred speech, drowsiness, dysphagia, restlessness, increased salivation, nausea, and proximal muscle weakness. The usual cause of death is respiratory failure.
Gila Monster

Gila monster bites are generally associated with pain, edema, and weakness. Hypotension is common with severe bites. Envenomation involves secretion of the venom from glands along the lower jaws. The venom is introduced into the victim through grooved teeth and a chewing mechanism. Gila monster bites are seldom fatal.17

Infection

Although snakebite envenomation has been stressed here, any bite or puncture wound carries a risk for bacterial contamination. Gram-negative organisms predominate when snake venom and mouthparts are cultured. Although several studies have shown that prophylactic antibiotics are not indicated for snakebite, tetanus, osteomyelitis, cellulitis, or gas gangrene may occur in cases of snakebite with or without envenomation. This is especially true when a large amount of local tissue destruction has occurred, treatment has been delayed, or inappropriate first aid was attempted.26

Management

Out-of-Hospital Care

All snakebites should be considered an emergency, and any victim should be medically evaluated. The initial 6 to 8 hours after a snakebite is critical. During this time, medical therapy can help prevent the morbidity associated with severe envenomation. Effective out-of-hospital care can be important.27

Out-of-hospital care is relatively simple if guided by four basic concepts. First, the estimated time until arrival at a medical facility, as well as the skill of the on-scene assistants, must be considered when instituting first aid. The victim should be separated from the snake if possible to prevent further bites. A stick, pole, or other object longer than the snake can be used to move the snake away from the victim or, if necessary, to kill the snake by striking it behind the head. Rapid transportation to a medical facility is the best first aid for a snakebite.

Second, spread of the venom should be slowed if possible; several methods are known. The patient’s excitement and physical activity, movement of the bitten area, alcohol consumption, and greater depth of the bite increase the spread of venom. Except for the last factor, these issues can be addressed by calming the victim, immobilizing the bitten area, and not giving anything by mouth. A new method of first aid for venomous snakebites has been developed in Australia. The immobilization and compression technique, also called the Commonwealth Serum Laboratory technique, slows uptake of Elapid venom and mock venom in humans. The bitten extremity is either wrapped in an elastic bandage or placed in an air splint. In another technique from Australia called the Monash method, a thick pad and bandage are placed over the bite wound and extremity. Both these techniques have similar postulated mechanisms of action: The lymphatic vessels and superficial veins are collapsed, and the proximal spread of venom is slowed. Although this method is successful as first-aid therapy for Elapidae bites, its use for pit vipers has not been demonstrated.28-30 If less than 30 minutes has elapsed since the bite, a constricting band applied tightly enough to impede superficial venous and lymph flow, but not arterial blood flow, may be used. The band should be loose enough to admit a finger between the band and the skin after application. It should be used with caution to prevent the development of a tourniquet effect under swollen tissue, which may cause more destruction than the snakebite.31 Incision of bite wounds should be avoided because of lack of proven efficacy and potential danger to underlying structures. The use of ice is not helpful in slowing the spread of venom, but an ice bag wrapped in a towel and applied to the bite area helps relieve pain. Ice water immersion and packing of the extremity in ice are dangerous and only contribute to tissue destruction. The use of suction devices has not been shown to be beneficial.32,33

Third, when feasible, the snake should be identified or brought to the treating facility with the victim. This should be done safely; usually, only experts should handle live snakes. Dead snakes can be placed in a hard container such as a bucket or ice chest. Care should be taken to not touch the head of the snake because envenomation can occur even after death. Live snakes should not be pursued to capture them. It is more important to get the victim to definitive medical care. Fourth, additional medical interventions should be initiated, if available. Cardiac monitoring, intravenous fluids, analgesics, and blood samples may be helpful, especially with signs of envenomation.

Emergency Department Care

Many snakes do not envenomate their victims when they bite, which has provided false support for the historical use of whiskey, clam juice, or split chickens for snakebite. The only proven therapy is antivenin. Emergency department care of a snakebite must focus on supportive care and rapid treatment with the appropriate antivenin. Rapid decision-making is required to determine the optimal type, amount, and route of administration of the antivenin. By the time the emergency physician examines a snakebite victim, the venom may have already caused much damage both locally and systemically. In this case, the emergency physician must be prepared to support the victim’s cardiovascular and respiratory systems.

The snake should be identified if possible, but this may not be easy. The presence of pits is the most consistent factor in identifying pit vipers, and the color pattern can help identify a coral snake. Most large cities have either zoos or herpetologic societies whose members can help identify exotic or unknown snakes. Fortunately, most victims of exotic snakebite are collectors and can positively identify the snake.

Patient History. Specific historical information should include time elapsed since the bite, the number of bites, whether first aid was administered and what type, location of the bite, and any symptoms (e.g., pain, numbness, nausea, tingling around the mouth, metallic taste in the mouth, muscle cramps, dyspnea, and dizziness). A brief medical history should include the last tetanus immunization, medications, and cardiovascular, hematologic, renal, and respiratory problems. An allergy history with emphasis on symptoms after exposure to horse or sheep products, previous injection of horse or sheep serum, and a history of asthma, hay fever, or urticaria should be obtained if considering antivenin treatment.

Patient Examination. The bite area should be examined for signs of fang marks or scratches and local envenomation (e.g., edema, petechiae, ecchymosis, and bullae). The area distal to the bite should be checked for pulses. A general physical examination should be performed with emphasis on the cardiorespiratory system. A thorough neurologic examination should be performed and recorded, especially if a Mojave rattlesnake, coral snake, or exotic snake is suspected. If the bite involves an extremity, the circumference of the extremity at the site of the bite and approximately 5 inches proximal to the bite should be measured and recorded. These data aid in objectively estimating both spread of the venom and the effect of antivenin (Fig. 59-3).
Grading Envenomation

- **Grade 0 (minimal).** There is no evidence of envenomation, but snakebite is suspected. A fang wound may be present.
- **Grade I (minimal).** There is minimal envenomation, and snakebite is suspected. A fang wound is usually present. Pain is moderate or throbbing and localized to the fang wound, surrounded by 1 to 5 inches of edema and erythema. No evidence of systemic involvement is present after 12 hours of observation. No laboratory changes occur.
- **Grade II (moderate).** There is moderate envenomation, more severe and widely distributed pain, edema spreading toward the trunk, and petechiae and ecchymoses limited to the area of edema. Nausea, vomiting, and a mild elevation in temperature are usually present.
- **Grade III (severe).** The envenomation is severe. The case may initially resemble a grade I or II envenomation, but the course is rapidly progressive. Within 12 hours, edema spreads up the extremity and may involve part of the trunk. Petechiae and ecchymoses may be generalized. Systemic manifestations may include tachycardia and hypotension. Laboratory abnormalities may include an elevated white blood cell count, creatine phosphokinase, prothrombin time, and partial thromboplastin time, as well as elevated fibrin degradation products and D-dimer. Decreased platelets and fibrinogen are common. Hematuria, myoglobinuria, increased bleeding time, and renal or hepatic abnormalities may also occur.
- **Grade IV (severe).** The envenomation is very severe and is seen most frequently after the bite of a large rattlesnake. It is characterized by sudden pain, rapidly progressive swelling that may reach and involve the trunk within a few hours, ecchymoses, bleb formation, and necrosis. Systemic manifestations, often commencing within 15 minutes of the bite, usually include weakness, nausea, vomiting, vertigo, and numbness or tingling of the lips or face. Muscle fasciculations, painful muscular cramping, pallor, sweating, cold and clammy skin, rapid and weak pulse, incontinence, convulsions, and coma may also be observed. An intravenous bite may result in cardiopulmonary arrest soon after the bite.

Onset of symptoms may be delayed and manifested as a variety of neurologic symptoms, including weakness, ptosis, stupor, bulbar paralysis, and other cranial nerve dysfunction, as well as nausea, abdominal pain, and headache.

**Administration of Antivenin.** Any victim of a venomous snakebite with moderate or severe envenomation is a candidate for antivenin. The choice of antivenin depends on the species of snake, and the antivenin may be horse serum- or sheep-derived Fab fragments. Wyeth Laboratories, producer of the polyclonal antivenin for Western Hemisphere pit vipers, no longer manufactures that antivenin. Many zoos and hospitals still maintain vials of this antivenin until it can be replaced with the ovine-derived Fab antivenin (FabAV). This antivenin is

*Dosage based on initial findings and clinical response to antivenin.
†If this dose elicits a clinical response, it is recommended to give an additional two vials at 6, 12, and 18 hours.
derived from four species of U.S. pit vipers and has not been studied with regard to bites from Mexican, Central American, or South American pit vipers. The Wyeth antivenin was derived from two U.S. species, one Mexican and Central American species, and one South American species and was efficacious against most of the world’s pit vipers. Most antivenin for exotic snakes is derived from horse serum, and the eastern coral snake antivenin is also horse serum derived. Skin testing was commonly performed before administering horse serum-derived antivenin, but it is not medically indicated because of the inaccuracy of the test. Moreover, testing with normal horse serum may precipitate an allergic reaction, and even a positive test may not preclude treatment if a patient has sustained severe envenomation.

**Dosage and Precautions**

1. Because anaphylaxis may occur whenever antivenin is administered, appropriate therapeutic agents (e.g., oxygen supply, airway support, epinephrine, and other pressors) must be ready for immediate use. Any patient requiring antivenin should have two intravenous lines inserted. If an allergic reaction occurs, the line with the antivenin can be clamped and the other line used for resuscitation. Administering 0.3 mg of 1:1000 epinephrine subcutaneously before administration of antivenin may prevent allergic reactions from horse serum-derived antivenin and, if not contraindicated, should be used.

2. The initial dosage of antivenin is prepared (see Table 59-3). The smaller the body of the patient, the larger the relative initial dose that may be required. A bitten child usually receives more venom in proportion to body weight and thus requires more antivenin to neutralize it. Because children seem to have less resistance and less body fluid with which to dilute the venom, they may require twice the adult dosage of antivenin. The total fluid requirements of children are less, however, so the antivenin should be given in a more concentrated solution. All antivenin should be administered intravenously.

3. Pregnancy is not a contraindication to antivenin therapy.

4. Administration of antivenin at or around the site of the bite is not recommended.

5. The need for subsequent doses is based on the patient’s clinical response. The patient is monitored closely after the initial dose, and local and systemic symptoms, as well as laboratory findings, are determinants of the need for further antivenin. Additional injections of one to five vials of antivenin are administered every 1 or 2 hours if symptoms progress. Most pharmacies do not stock large amounts of antivenin, and the pharmacy should be notified to obtain additional antivenin for treating a severe bite.

6. Even with a history or signs of allergy, patients with severe envenomation should be treated with a dilute form of antivenin and epinephrine.

Current treatment of pit viper envenomation in the United States is to use an FabAV polyvalent antivenin rather than the horse serum product. This is designed to limit the allergic reactions associated with horse serum antivenin by using antigen-binding fragments (Fabs) of sheep (ovine) immunized against four species of venomous snake found in the United States. CroFab has been shown to be as effective as the Wyeth antivenin, with fewer allergic reactions. Because of more rapid clearance of smaller Fab fragments by the kidney, however, a repeat dose regimen must be used to prevent the recurrence of coagulopathy. The duration of action of the venom may be longer than the therapeutic effect of the antivenin. Initial studies have shown promise for a new affinity-purified, mixed monospecific ovine Fab antivenin. This product has been tested with favorable results in humans after minimal to moderate crotalid envenomation. Its efficacy in pit vipers from South America or Asia has not been proved, nor has its usefulness for copperhead bites. Purification of antivenin by separation of active fractions may lead to safer administration of horse serum-derived antivenin. In the next decade, snakebite management will probably change radically throughout the world. Phyotherapy (botanical therapy) and other non-antivenin drug therapies for snakebite have been shown to be efficacious in experimental animals, and some centers have successfully treated snakebite with medical support only.

The use of enzyme-linked immunosorbent assay in the diagnosis of Viperidae and Elapidae bites, especially in Australia, Asia, and Africa, has led to more certain criteria for identifying the responsible snake in a patient with suspected envenomation. Active immunization against specific snakes, similar to that for certain jellyfish and hymenopterans, is being attempted in the Amami Islands.

**Coral and Exotic Snakes.** All victims of bites by the *eastern coral snake* (*Micrurus fulvius*) should be given antivenin (also manufactured by Wyeth) even before any symptoms develop. The toxicity of this venom has a rapid onset, and once symptoms develop, it may be too late to reverse the effects with antivenin. The recommended dose is three to five vials in 300 to 500 mL of normal saline. Antivenin should be given based on the clinical response. No antivenin exists for the venom of the *Arizona (Sonoran) coral snake*, which fortunately is less dangerous. Treatment of this type of snakebite is supportive.

The problems with bites of exotic snakes are threefold: Positive identification of the specimen is sometimes difficult, even for experts; specific antivenin is not always readily available; and even if the antivenin is available, the instructions for reconstitution and dosage may not be written in English. Many zoos maintain a supply of antivenin for their venomous snakes, and this may be the best source of antivenin for an exotic species. Some collectors keep appropriate antivenin on hand for the species that they collect. The Antivenin Index at the Arizona Poison Center (602-626-6016) can assist in identifying sources of exotic antivenin or in obtaining more pit viper antivenin. As with coral snakes, many patients do not show any early signs after envenomation by exotic snakes. The antivenin should be administered before neurologic changes develop.

**Wound Care.** The wound should be cleansed and immobilized. Elevation at or above heart level may relieve some of the pain. If the snake is a pit viper and the wound is on an extremity, a constricting band that does not occlude arterial blood flow may be applied proximal to any swelling caused by the bite. A constricting band should not be applied, however, if more than 30 minutes has elapsed since the bite occurred. Some authors have previously advised excision of the bitten area, but such management is no longer recommended. As with any puncture wound, patients should be immunized against tetanus. Broad-spectrum antibiotics have not been shown to be useful in uncomplicated snakebites. If there has been a long delay in treatment or if signs of secondary infection develop, ampicillin-clavulanate can be administered. Analgesics should be given as needed to relieve severe pain. The wound should be examined for remains of embedded fangs or teeth, and these should be removed.

Patients admitted to the hospital should have the previously mentioned laboratory tests performed and then serial determinations of platelets, fibrinogen, prothrombin time, and urinalysis every 4 hours to check for myoglobin and hemoglobin. Blood products should be administered, including packed red
PART II  Trauma / Section Four  •  Soft Tissue Injuries

blood cells, fresh frozen plasma, and other coagulation factors as needed. Usually, it is best to wait until antivenin therapy has been started, or the use of the blood products may be futile. Daily comprehensive laboratory tests should be performed. Awake patients who have no nausea or abdominal pain can be given oral fluids. Local wound care should involve daily cleansing with soap and water and the application of a sterile dressing. Surgical consultation should be obtained for débridement or skin grafting. Fasciotomy is not usually indicated unless compartment pressures are elevated above 30 mm Hg and signs of compartment syndrome are present. Débridement should probably not be performed earlier than 3 days after the bite, until the coagulopathy has resolved. Surgical exploration of the bite wound is not necessary and may be harmful. Skin grafts are occasionally necessary after bites by pit vipers that produce large necrotic areas. Physical therapy is often needed and should begin soon after the acute phase of the envenomation is complete.

Serum Sickness. In most patients who receive more than 10 vials of horse serum-derived antivenin and in approximately 15% of those who receive FabAV, serum sickness develops up to a week later. The administration of diphenhydramine plus cimetidine, and in severe cases a tapering dose of steroids, can be used to treat this problem. Serum sickness is the only indication for the use of steroids with snakebite.14-45

Other Envenomation. Gila monster and Mexican beaded lizard bites are treated similar to pit viper bites with regard to first aid. No definitive medical treatment exists. Antivenin is currently not available. Local wound care, tetanus prophylaxis, the use of antibiotics and analgesics, and supportive care are the extent of emergency department treatment available for this type of envenomation.17

Envenomation by the yellow-bellied sea snake causes severe muscle necrosis with the release of large amounts of myoglobin and neurologic symptoms. Although a polyvalent antivenin is available from Australia, maintenance of adequate urine output, alkalinization of urine, and general supportive care are usually sufficient.10,35

Disposition
If no envenomation is evident after clinical examination and the snake was either nonvenomous or a pit viper, the victim can be observed for 6 to 8 hours. With some snakebites, however, toxicity may be delayed by up to 8 hours. If no sign of envenomation is seen after 8 hours, the patient may be discharged. These patients should be given tetanus immunization and wound care instructions and referred for follow-up within 24 to 48 hours. They should be told to return to the emergency department immediately if any symptoms of envenomation develop.

If only local pain and minimal edema have occurred and the snake is thought to be nonvenomous or a pit viper, the patient should be closely watched for 12 hours in the emergency department. Then, if the pain and swelling have decreased and no systemic symptoms have developed, the patient may be treated with the same precautions as a patient with no signs of envenomation. Any patient with moderate or severe envenomation should be admitted to an intensive care unit for constant monitoring during antivenin therapy. Depending on the severity of the bite, blood products, vasopressors, and invasive monitoring may be necessary.

Any patient bitten by a coral snake, a Mojave rattlesnake, or an exotic snake is at risk for severe neurologic sequelae that may not become evident for many hours. As a result, the patient should be admitted to the hospital, preferably to an intensive care unit where he or she can be monitored closely. Arrange-ments should be made to have a ventilator, Swan-Ganz catheter, and dialysis equipment available if necessary. Appropriate antivenin should be obtained and treatment initiated at the earliest onset of symptoms. Some experienced clinicians may wait until symptoms develop before administering antivenin.

VENOMOUS ARTHROPODS

Arthropods are animals with segmented bodies and jointed appendages. This phylum (Arthropoda) contains approximately 80% of all known animals. Arthropods first appeared in the Cambrian period of the Paleozoic era 600 million years ago. The living members of this phylum are categorized into 12 classes. Two classes, the Insecta and the Arachnida, are of particular interest because numerous venomous species have evolved that are harmful to humans. Many species have developed venom glands and an apparatus for delivering the venom to obtain food. Others have developed venom delivery systems used solely for defense, most of which are found in the order Hymenoptera.18

Arthropods account for a higher percentage of deaths from envenomation than do snakes. They are found inside dwellings, as well as in deserts, forests, and lakes. Although most arthropods are more active in April through October, many are active throughout the colder months. Arthropods are also active 24 hours a day, and many can fly, thus increasing their range. This high level of contact results in millions of cases of envenomation annually. Most fatalities result from an autopharmacologic response by the victim rather than the toxicity of the venom. An individual stung by a bee may have a small amount of pain and local swelling or, in severe cases, an anaphylactic reaction and death.

Arthropods use three main methods of delivering venom: stinging, biting, and secreting venom through pores or hairs. Some arthropods combine two systems, one for offense and the other for defense. Generally, venom systems found on the oral pole of an animal are used for offensive purposes or food acquisition, whereas systems found on the caudal pole are used for defense. Humans are not considered prey for any venomous animal, and therefore bites from venomous animals are defensive, accidental, or reflexive. Many venomous arthropods are omitted from this discussion because of their infrequent contact with humans or the relative impotence of their venom.24,48,49

Hymenoptera

Hymenoptera is a familiar order of arthropods that is composed of the families of bees, wasps, hornets, yellow jackets, and ants. Many of these species are social insects, and their defense response is related to protection of the group rather than the individual organism. Although most members of this order are stinging insects, several species of ant can bite and sting simultaneously.

Bees and wasps have similar mechanisms of delivering venom. Female insects of this type have modified ovipositors that protrude from the abdomen and act as hypodermic needles to administer the venom. The barbed stinging apparatus of the bee is quite prominent. The stinging action pulls the stinger from the bee, thereby eviscerating the insect and killing it.28

The wasp, which has an unbarbed stinger, may inflict many stings without damaging itself or its stinging apparatus. The venom is produced in one or two tubular glands that empty into a venom reservoir. The venom reservoir has a duct that connects to the stinger. The venom is composed of several classes of substances varying in composition among different species. Proteins, as in snake venom, make up most of the
venom by dry weight. Peptides, amino acids, carbohydrates, lipids, and other low-molecular-weight substances are also found. The most common enzymes are phospholipase A and hyaluronidase. Peptides are common in some species and comprise up to 50% of the dry weight. Most of the toxicity of the venom results from substances of low molecular weight (e.g., bradykinin, acetylcholine, dopamine, histamine, and serotoin). Many other antigenic substances have been identified in bee and wasp venom, and they account for the induction of hypersensitivity and anaphylaxis in humans.\(^{21,51-53}\)

**Clinical Features**

The signs and symptoms of bee and wasp stings vary, depending on the degree, type, and location of envenomation, as well as the characteristics of the victim. Bee and wasp venom can cause serious injury other than allergic types of reactions, depending on the number of stings, the species of insect, the size and previous health of the victim, and the anatomic area stung. For example, a sting in the tongue or throat may quickly compromise the airway. Honeybee venom causes a much greater release of histamine per gram than does other hymenoptera venom and thus is more dangerous. Certain species of honeybee release a pheromone, isoamylacetate, when the ovipositor is pulled from the abdomen after stinging a victim. This pheromone attracts other bees to the victim and thus incites multiple stings.

There is little antigenic overlap between species, which may explain the variability in reaction to stings reported by victims. Victims who are allergic to honeybees and who mistakenly identify a yellow jacket as a honeybee may not have a systemic reaction and thus may think that they are no longer allergic to honeybees.\(^{54-56}\)

The most consistent finding is immediate pain at the site of the sting, followed by local swelling, redness, and itching. A sensitive victim may experience swelling, urticaria, coughing, wheezing, coma, and respiratory arrest. Some large and especially venomous hornets have been known to cause muscle necrosis and renal damage. Most serious reactions to bee stings occur in the first 30 minutes; however, the local effects of a sting may persist for 2 or 3 days. Delayed hypersensitivity may occur 7 to 10 days after the sting.

**“Killer Bees.”** Health officials have been concerned about a particularly aggressive species of bee imported from Africa to Brazil in 1956 that has been known to attack humans and cattle with fatal results. This bee has managed to compete with native species and is gradually replacing some of these species while still retaining its aggressive behavior. Envenomation from these aggressive arthropods is most dangerous to very young or elderly patients and those with concomitant medical conditions.\(^{57}\) Killer bees have colonized northern Mexico and have moved into the southern United States, including California, Arizona, and Texas, where the mean high temperature is at least 60°F.\(^{58,59}\) This type of bee is not more toxic, only more aggressive.

**Fire Ants.** Another unwelcome import to the United States is the fire ant. This insect is a member of the family Formicidae and is another of the Hymenoptera that is harmful to humans. Several species of fire ant are known, some native to North America and some imported. The species responsible for 95% of clinical cases, *Solenopsis invicta*, was imported from Brazil to Alabama in the 1930s. This ant is now found in nine southern states and is replacing many native species and inhabiting new niches. The only limiting factor keeping the fire ant from progressive migration seems to be cold winters. This ant is small and light reddish brown to dark brown. Its venom is unique to the animal kingdom in that it is 99% alkaloid. The remaining 1% is quite immunogenic and can sensitize an individual to the venom. Properties of this venom include hemolysis, depolarization of membranes, activation of the alternative complement pathway, and general tissue destruction. The sting is produced when the ant bites the victim with its jaws and, while holding tight, pivots around and stings the victim with its ovipositor. The sting usually produces a sterile pustule within 24 hours. Other symptoms include local burning, redness, and itching. With multiple stings and in sensitive individuals, urticaria, angioedema, dyspnea, nausea, vomiting, wheezing, dizziness, and respiratory arrest may occur. Approximately 10% of victims have some degree of hypersensitivity reaction.\(^{60-62}\)

**Management**

**Home Care.** First aid for Hymenoptera envenomation depends on the degree of reaction to the sting. With simple stings, an ice bag wrapped in a towel and applied to the sting area usually relieves the pain and swelling. In the event of an anaphylactic reaction, basic life support should be administered until further medical help can be obtained. Many people allergic to Hymenoptera envenomation carry an emergency insect sting kit containing a tourniquet, epinephrine in a 1:1000 dilution, and an antihistamine. These kits are readily available, and both the patient and the patient’s family should be instructed in the treatment of a severe allergic reaction.

**Emergency Department Care.** No specific antivenin exists for Hymenoptera stings. Treatment consists of local wound care and general supportive measures. A history of any previous allergic reactions to bee stings, hay fever, asthma, or drug reactions should be obtained. The circumstances surrounding the sting and the number and location of stings should be noted. A patient with a single sting and only a local reaction should have the sting area inspected for evidence of a venom apparatus, which is removed by scraping the edge of a scalpel blade parallel to the skin and lifting the apparatus away from the skin without squeezing the venom sac. An ice bag wrapped in a towel may then be applied and the patient given an oral antihistamine (e.g., 50 mg of diphenhydramine). The patient should be monitored and, if no further reaction is observed, may be discharged with instructions to return to the emergency department if wheezing, dyspnea, hives, dizziness, and/or dysphagia occurs.

Adults in whom a severe urticarial reaction, dyspnea, or hypotension develops should be given 0.3 mL of epinephrine in a 1:1000 dilution intramuscularly, 50 mg of diphenhydramine intravenously, and 50 mg ranitidine intravenously. Patients with severe hypertension, cerebrovascular disease, or heart disease should be given epinephrine cautiously because of the potential for adverse reactions. Children should be given 0.01 mL/kg based on their body weight of a 1:1000 dilution of epinephrine intramuscularly and 1 mg/kg of diphenhydramine intravenously. These patients must be watched closely for signs of respiratory problems and treated accordingly. After 1 hour, these individuals should be totally free of symptoms (except for some itching around the sting site). Any patient requiring epinephrine should be watched for 24 hours due to recurrent allergic reaction. There is a possibility of recurrence of the reaction up to 72 hours and patients should be warned of this. They should be given the same instructions as patients with a minor reaction. Patients with allergic reactions to a single sting should be given an emergency insect sting kit and instructed in its use. They may be referred to an allergist for desensitization.

Wheezing should be treated with a beta-agonist given by hand-held nebulizer and repeated as necessary. A second
large-bore intravenous line with normal saline should be established. These patients should be monitored closely and given an intravenous steroid plus 50 mg of diphenhydramine and 50 mg of ranitidine intravenously. Admission is warranted for any severe anaphylactic reaction. Patients who have life-threatening reactions (hypotension, respiratory arrest, and cardiac arrest) may be given 0.1 mg of epinephrine in at least a 1:10,000 dilution, very slowly intravenously. The intramuscular route should be used for all but the most extreme reactions.

Treatment of allergic reactions to fire ant stings is the same. The skin lesions should be kept clean with soap and water. Ice bags may be applied initially to relieve burning and pain. Prophylactic antibiotics are not needed.

Of patients who have a systemic reaction to an insect sting, 60% can have a future allergic reaction if they have a positive skin test. These patients should be desensitized to any specific venom to which they are allergic. Purified insect venom is currently available for most Hymenoptera, including fire ants.63 Prophylactic antibiotics are not needed.

Patients seen in the emergency department with systemic reactions to stings should be referred for skin testing and desensitization. These patients should be given emergency insect sting kits with instructions for use and should avoid activities that place them in proximity to Hymenoptera species.54-56,64

**Spiders and Scorpions**

The class Arachnida contains the largest number of venomous species known, with approximately 34,000 species of venomous spiders and 1400 species of venomous scorpions. Virtually all known species are venomous, but most are not harmful to humans. Only approximately 50 species of arachnids in the United States cause human illness because most species do not have fangs or stingers sufficiently long to penetrate human skin. Humans fear spiders and scorpions, which is well founded in certain cases. Ticks, which also belong to this class, are less feared but probably cause more morbidity because of transmission of infectious diseases such as Rocky Mountain spotted fever and Lyme disease. Some spider bites are never diagnosed because of lack of significant symptoms and the fact that they occur while the victim is sleeping. Many non-spider bites are incorrectly diagnosed as spider bites, and unfortunately, there is no gold standard for making the diagnosis.

**Black Widow Spider**

The black widow spider, Latrodectus mactans, may be the most recognized venomous spider in the world. Several closely related species of *Latrodectus*, or widow spiders, are found throughout the United States, including *Latrodectus hesperus*, which is common in Arizona and other western states. The diagnosis and treatment of the bites of all species are the same.

The black widow is found throughout the United States (except Alaska) and in southern Canada. The female is approximately twice as large as the male, and although both are venomous, only the female is able to envenomate humans. The black widow is glossy black, occasionally with red stripes, and has a bright red marking on the abdomen. This marking may have an hourglass shape or may appear only as two spots. Abdominal markings may vary, and related *Latrodectus* species may be similar in appearance and toxicity. The combined length of the black widow’s head and abdomen is approximately 0.5 inch, and the spider is approximately 1.5 inches long, including the legs. It is found in protected places such as under rocks, in woodpiles, and in outhouses and stables. The female is not aggressive except when guarding her eggs.

The venom apparatus of the black widow is a modified first appendage of the head known as the chelicera. The spider is able to control the amount of venom injected into its prey. The venom of the black widow is complex and contains both protein and nonprotein compounds.

Spiders normally use the venom to paralyze their prey and also to liquefy the tissues of the prey for digestion. The venom probably evolved from digestive glands analogous to the salivary glands in snakes. The ingredient most toxic to humans is thought to be a neurotoxin. This toxin destabilizes neuronal membranes by opening ionic channels, causing depletion of acetylcholine from presynaptic nerve terminals and increasing the frequency of spontaneous miniature endplate potentials at neuromuscular junctions.21,65

**Clinical Features.** The classic symptomatology of the black widow bite is initially a pinprick sensation that may be followed by minimal local swelling and redness. If the area is examined closely, two small fang marks may be noticed. Sometimes the bite is not felt, especially if the victim is working when the bite occurs. From 15 minutes to 1 hour later, dull crampy pain develops in the area of the bite and gradually spreads to include the entire body. Usually, the pain is concentrated in the chest after upper extremity bites or in the abdomen after lower extremity bites. The abdomen may become boardlike, and the patient may complain of severe crampy pain. The abdominal manifestation may mimic pancreatitis, a peptic ulcer, or acute appendicitis, except that abdominal tenderness is usually minimal. Pregnant women may go into premature labor and precipitous delivery. Associated symptoms include dizziness, restlessness, ptosis, nausea, vomiting, headache, pruritus, dyspnea, conjunctivitis, facial swelling, sweating, weakness, difficulty speaking, anxiety, and cramping pain in all muscle groups. The patient is usually hypertensive, and cerebrospinal fluid pressure is sometimes elevated. There may be electrocardiographic changes similar to those produced by digitalis.18,21,66

In adults, the signs and symptoms begin to abate after several hours and usually disappear in 2 or 3 days. A small child bitten by a black widow spider, however, may not survive.67 As with snake envenomation, the volume of distribution of black widow venom is much smaller in children than in adults. A dose that may cause only a few hours of pain in an adult may lead to complete cardiac decompensation and respiratory arrest in a child. Adult patients with preexisting hypertension, cerebrovascular disease, or cardiovascular disease are also at greater risk for complications. Symptoms usually persist for 8 to 12 hours and then subside, although in severe cases muscle cramps may continue for several days.

**Management.** First aid for a black widow spider bite consists of applying an ice pack to the bite area for relief of pain and transporting the victim to a hospital where supportive, symptomatic, and definitive treatment can be administered. The rescuer should obtain the specimen if possible because many dangerous spiders resemble harmless species and vice versa. The patient should be monitored closely en route to the hospital and basic life support initiated if necessary. Bites in the neck or mouth area may cause airway compromise through muscle spasm. Emergency department care consists of obtaining a history of the circumstances surrounding the bite, a description of the appearance of the spider, any significant past medical history, current medications, and allergies to insect bites, horses, or horse serum.

The wound site should be inspected for fang marks and cleansed with soap and water. As with any puncture wound, tetanus immunization should be instituted. The patient should
be observed for approximately 6 hours. If symptoms do not develop and the spider was not positively identified as a black widow, the patient may be discharged with instructions to return to the emergency department if any symptoms develop.

All patients with symptoms of moderate envenomation, pregnant women, children, and those with preexisting cardiovascular disease or hypertension should be admitted to the hospital, have intravenous lines inserted, and have a complete blood count, electrolytes, blood urea nitrogen, creatinine, coagulation studies, urinalysis, and an electrocardiogram performed. Acute hypertensive problems should be treated with nitroprusside if diastolic pressure rises above 120 mm Hg.

Symptomatic treatment usually involves controlling the muscle cramps responsible for most of the discomfort associated with the bite. Diazepam or other benzodiazepines given intravenously are useful for relieving muscle spasms. Dantrolene sodium has been used both orally and intravenously to provide muscle relaxation for *Latrodectus* envenomation. Parenteral analgesics may be necessary to control pain. These drugs may affect an already compromised respiratory condition; thus, their use must be closely monitored. Patients with moderate symptoms should be admitted to the hospital and monitored until symptoms subside; usually 1 day is sufficient. Pregnant women should undergo fetal monitoring, and those with severe symptoms should be admitted to an intensive care unit with cardiovascular monitoring.

**Latrodectus Antivenin.** In general, pediatric patients, pregnant women, and the elderly may need to be given *Latrodectus* antivenin (Lyovac), which is derived from horse serum. Clinical judgment must be used to adjust for the age and category of patients needing antivenin. Antivenin should be administered to patients with severe envenomation manifested as seizures, respiratory failure, or uncontrolled hypertension; to pregnant women; and to patients not responding to other therapy. The dose of the antivenin is one vial diluted in 50 mL of normal saline and administered intravenously over a period of 15 minutes. Precautions for allergic reactions should be taken before administering antivenin. A dose of subcutaneous 1:1000 epinephrine may prevent allergic reactions when given before horse serum antivenin. This antivenin is also useful with other species of the *Latrodectus* genus.

### Brown Recluse Spider

Several deaths were attributed to the brown recluse spider, *Loxosceles reclusa*, in the 1950s, primarily in the south-central United States, thus drawing the attention of the medical community. Many species of *Loxosceles* are venomous to humans, and at least five are found in the United States. These spiders are approximately 1 inch long, including leg span, and range in color from tan to dark brown. The most distinguishing mark is a violin-shaped darker area found on the cephalothorax. Close examination may reveal that the brown recluse has three pairs of eyes rather than the usual four.

These spiders, as their name implies, are not aggressive and are usually found under rocks, in woodpiles, and occasionally in attics and closets. Their range is concentrated in the south-central United States, especially Missouri, Kansas, Arkansas, Louisiana, eastern Texas, and Oklahoma. However, they have been reported in several large cities outside this range.

The venom apparatus is similar to that of most spiders, including the black widow. The composition of brown recluse venom has not been completely determined, but sphingomyelinase D is a primary component. The local tissue destructive effects are thought to be primarily caused by hemolytic enzymes and a levarterenol-like substance that induces severe vasoconstriction. The systemic symptoms seem to be an allergic phenomenon and vary according to the individual’s immune response to the venom.

**Clinical Features.** The symptoms of a brown recluse spider bite are both local and systemic. Initially, they are similar to those caused by bites of many other spiders and other conditions, including pyoderma gangrenosum, furuncles, viral and fungal infections, and foreign body reactions. The victim may notice some burning pain in the area of the bite. Some victims do not notice the initial bite at all. Pain usually develops within 3 or 4 hours, and a white area of vasoconstriction begins to surround the bite. A bleb then forms in the center of this area, and an erythematous ring arises on the periphery. The lesion at this stage resembles a bull’s-eye. The bleb darkens, necroses over the next several hours to days, and continues to spread slowly and gravitationally, with involvement of skin and subcutaneous fat. The most common mimic of *Loxosceles* or other necrotic spider bite is a methicillin-resistant *Staphylococcus aureus* (MRSA) skin infection.

Systemic symptoms include fever, chills, rash, petechiae, nausea, vomiting, malaise, and weakness. Hemolysis, thrombocytopenia, shock, jaundice, renal failure, hemorrhage, and pulmonary edema are the usual signs of severe envenomation. Fatalities are more common in children, most often the result of severe intravascular hemolysis.

**Management.** First aid for a brown recluse spider bite is simple. The specimen is secured if possible and the victim transported to a medical facility. Because the lesion develops over a period of days, there may not be any local treatment of the lesion that is effective. The physician should try to determine whether any systemic toxicity is present. A history of the circumstances surrounding the bite, the time elapsed since the bite, and any past history of allergic reactions, medications, or medical problems should be obtained. If a specimen is available, an attempt should be made to identify it. The assistance of a local entomologist should be obtained if necessary. If signs of systemic toxicity develop, an intravenous line should be placed in an unaffected extremity, and a complete blood count, electrolyte levels, blood urea nitrogen level, and creatinine level should be determined and coagulation studies and urinalysis performed. The patient who presents several days after the bite due to tissue injury should have the wound cultured to rule out MRSA and washed with soap and water, and tetanus prophylaxis should be given. Vital signs and urine output should be monitored closely. Excision of the lesion has not been shown to aid healing and may be detrimental. Lesions have been known to cause extensive scarring, infection, and necrosis. Bites that are in fatty areas, such as the thigh or buttocks, may cause more extensive necrosis. Dapsone, 50 to 200 mg/day, has been shown to be helpful in preventing local effects of the venom. If used within 48 hours, it may limit the size of the lesion that develops. However, dapsone may cause methemoglobinemia and hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency. Hyperbaric oxygen has been shown to decrease lesion size in animals. Analgesics and antibiotics should be used as indicated during the course of the disease, although infection is not common. All patients with signs of systemic envenomation should be admitted to the hospital and monitored closely with daily blood counts, urinalysis, and urine output. Dialysis may be necessary if acute renal failure develops, and surgical consultation should be obtained for evaluation of the wound.

The Instituto Butantan in Sao Paulo, Brazil, produces an antivenin for *Loxosceles* bites, but it is not available in the United States. Research is being conducted to produce a rabbit serum antivenin against *Loxosceles*, but it is not yet commercially available.
Other Spiders

Several other spiders can cause envenomation but are uncommon in the United States. Some of these spiders are large and can be quite aggressive. Most are imported either intentionally or as stowaways on cargo ships. Tarantulas, wandering spiders, funnel-web spiders, pallid spiders, and crab spiders are a few of the imported venomous spiders. Many of these species can cause envenomation similar to that of the brown recluse spider, and some produce neurotoxins.

Antivenin is produced for some of these groups (e.g., Brazilian Phoneutria spp. and Australian Atrax spp.) but is usually available only in the country where the species is generally found. Emergency care therefore involves symptomatic and supportive treatment. An outbreak of bites by a species of Tegenaria, known as the hobo or aggressive house spider, has been reported. This species was imported from Europe to the Pacific Northwest. This spider is a small brown spider with a herringbone pattern on its abdomen. The lesions are similar to those caused by the brown recluse spider, but systemic symptoms include headache and weakness. Treatment is largely supportive.

Tarantulas are popular pets in the United States, and most native species are relatively nontoxic. Tarantulas are unusual in that the abdominal hairs can be thrown by the spider and embedded in human skin and the eye. These hairs can cause allergic reactions and severe conjunctivitis and must be removed under a slit lamp or by an ophthalmologist. A recent import from Thailand, the cobalt blue tarantula, Haplopelma lividum, is a very aggressive spider with toxic venom.

Scorpions

Scorpions are arachnids that resemble crustaceans and are among the oldest terrestrial animals. Scorpions are found throughout the world, and several species are located in the southwestern United States. Only one species, Centruroides exilicauda, which is found in Arizona, is particularly dangerous. Scorpions are nocturnal predatory animals that usually spend the day under rocks, logs, or floors and in crevices. Centruroides exilicauda, or the “bark scorpion,” is found on or near trees (Fig. 59-4).

The scorpion has a tail-like structure that is actually the last six segments of its abdomen. The last segment, or the telson, contains the two venom glands and stinger. The toxicity of scorpion venom varies greatly from species to species. Generally, the less dangerous species produce more local reactions, and the more dangerous species cause more systemic reactions. Several proteins have been identified in their venom; some cause hemolysis, local tissue destruction, and hemorrhage. The venom of *C. exilicauda* is predominantly a neurotoxin that causes or enhances repetitive firing of axons by activation of sodium channels.

**Clinical Features.** Envenomation causes severe and immediate pain at the sting site. Local edema and erythema may or may not be present, depending on the species. After envenomation by *C. exilicauda*, the victim may have heightened sensitivity to touch in the area of the sting along with local numbness and weakness. The diagnosis is often made by tapping on the site of the sting and causing an increase in pain at the site. Systemic symptoms may then develop, including anxiety, restlessness, muscle spasms, nausea, vomiting, excessive salivation, sweating, itching of the nose and throat, hyperthermia, blurred vision, myoclonus, hypertension, hemiplegia, syncope, cardiac dysrhythmias, and respiratory arrest. Various systemic complications may occur, depending on the species of scorpion. *Tityus trinitatus* scorpion stings cause pancreatitis to develop in 80% of its victims. A wave of symptoms sometimes occurs over a 24-hour period, or respiratory failure may develop in the first 30 minutes. As with most envenomation, children are at a greater risk for severe reactions. A grading system has been developed to guide management of bark scorpion stings.

**Management.** First aid for a scorpion sting consists of applying an ice bag to the area of the sting and transporting the victim to the hospital. A history of the circumstances surrounding the bite, any previous medical problems, and a description of the scorpion if no specimen is present should be obtained. It is relatively difficult for a layperson to differentiate the various scorpions. For *C. exilicauda* envenomations that occur in Arizona, a goat-derived non–Food and Drug Administration–approved antivenin is available from the Antivenom Production Laboratory of Arizona State University. Expert advice should be obtained before the use of this antivenin. A new antivenin is currently being evaluated in children. Narcotic analgesics and barbiturates have been reported to increase the toxic effects of the venom and should be avoided.

Antivenin should be given in all cases of severe envenomation. All victims should be observed for 24 hours, and children should be admitted to the hospital and monitored closely. Intravenous diazepam or another benzodiazepine may be used for myoclonus and muscle spasms. Phenobarbital, previously used in large doses in children, may be more dangerous than efficacious and may have contributed to deaths in the past. Atropine may be administered to control hypersalivation and bradycardia. Nitroprusside and prazosin have been used to control hypertension. Ventilatory assistance may be necessary, especially in children.

**Other Arthropods**

Ticks have been known as vectors of human disease for some time. Certain female ticks also secrete a toxin that causes a progressive ascending paralysis in humans and animals. The precise mechanism and structure of the toxin are unknown. The two species responsible in the United States are Derma- centor andersoni (wood tick) and Dermacentor variabilis (dog tick). The bite of the tick is usually painless, but the victim later has difficulty walking, weakness, flaccid paralysis, slurred speech, and visual disturbances. The victim is usually a child, often with a history of recent outdoor activity. Treatment is removal of the offending tick before the paralysis has progressed too far. Any patient seen with ascending paralysis...
should be closely examined for the presence of a tick, especially on the head and back.

Several species of beetle, millipede, and caterpillar secrete irritating substances that cause severe burning pain, numbness, purulent contact dermatitis, edema, nausea, vomiting, and headache. Oropharyngeal exposure can cause mucosal edema and irritation.\(^8^3\) No deaths have been reported. Treatment consists of washing the area thoroughly with soap and water and removing any spines or hairs present. Spines can be removed with adhesive tape or by applying white glue or facial peel. Locally applied ice bags and baking soda and water paste may be of benefit. Analgesics should be used as needed, and supportive therapy may be necessary for severe envenomation.

Centipedes can inflict bites causing erythema and edema. Treatment is usually local soaks and the use of analgesics. Conenose bugs, or “kissing bugs,” may cause severe local and systemic allergic reactions. Treatment with antihistamines and supportive care, depending on the degree of reaction, are all that is necessary. Many other arthropods can cause local skin reactions and severe allergic reactions, depending on the individual’s sensitivity. These patients should be treated symptomatically with local steroid creams, antihistamines, and other symptomatic supportive measures.\(^8^3\)

### VENOMOUS MARINE ANIMALS

#### Epidemiology

Almost 2000 species of animals found in the ocean are either venomous or poisonous to humans, and many can produce severe illness or fatalities. An estimated 40,000 to 50,000 marine envenomations occur annually. In recent years, the number of injuries caused by these animals has increased dramatically because of the greater number of scuba divers, snorkelers, surfers, and others engaging in water sports. These animals are not usually aggressive, and many are completely immobile. Most of the venomous marine animals injure humans with defense or food-procuring devices. Most venomous marine animals in the United States are found along the California, Gulf of Mexico, and southern Atlantic coasts. These animals range in complexity from sponges to bony fishes and contain some of the most complex and toxic venoms known.\(^2^0\)

#### Venom Delivery

In general, venomous marine animals may be divided into three main classes according to the mechanism of venom delivery: bites, nematocysts, and stings.

#### Bites

Biting animals include several species of cephalopods, most often octopi. Although popular media portray a giant deadly creature that squeezes its victims to death, the most dangerous octopi are seldom larger than 20 cm. Several fatalities have been reported after a bite by the blue-ringed octopus, *Hapalochlaena maculosa*. Most victims are bitten on the upper extremity as they disturb this normally nonaggressive creature. The octopus has a pair of modified salivary glands that secrete venom into the wound produced by the animal’s beak.\(^7^5\) The venom contains a potent vasodilator and an inhibitor of neuromuscular transmission similar to tetrodotoxin.\(^9^4,9^5\) No known antivenin exists, and treatment is largely supportive, with respiratory support the most important lifesaving intervention.\(^9^6,9^7\)

#### Nematocysts

The second type of venom mechanism is the nematocyst found in coelenterates (Cnidaria). This group of animals includes the Portuguese man-of-war, true jellyfish, fire corals, stinging hydroids, sea wasps, sea nettle, and anemones. Most of these organisms are sessile, but some are free floating. Because of their large numbers, this group accounts for the greatest number of envenomations by marine animals.\(^1^8\)

Many different types of nematocysts are known, but the basic mechanism is a “spring-loaded” venom gland that can, on mechanical or chemical stimulation, suddenly evert and discharge a structure that penetrates the prey and delivers the venom through a connecting tube. These nematocysts, found on the animal’s tentacles, can number in the hundreds of thousands. Tentacles can be up to 100 feet long in some giant species. Nematocysts can still function even if the animal is dead or if the tentacles are separated from the animal’s body. These stinging cells can remain active for weeks after an animal becomes beached. Often, not all nematocysts fire on initial contact but may discharge later during attempted rescue and treatment. Certain marine species have evolved methods of using ingested nematocysts for their own defense.

**Toxicity.** Nematocyst venom contains various peptides, phospholipase A, proteolytic enzymes, hemolytic enzymes, quaternary ammonium compounds, serotonin, and other toxic compounds. The venom of the coelenterates is antigenic, and allergic reactions are often seen. The severity of the envenomation is related to several factors. First, the severity of the injury is directly proportional to the number of nematocysts discharged. Second, the toxicity varies from species to species. It is unlikely that the victim or the treating physician will be able to identify the species from the appearance of the wound. Symptoms may range from simple isolated stinging to respiratory paralysis, cardiovascular collapse, and death. Therefore, the diagnosis must be made according to the clinical findings. Third, the victim’s autopharmacologic response to the venom may turn a relatively minor envenomation into a fatal anaphylactic reaction. Any clinician who regularly treats this type of injury should become acquainted with the common species in the particular area.\(^9^7\)

Although lethal and potentially lethal jellyfish occur worldwide, the extremely toxic specimens are found off the coast of Australia and in other Indo-Pacific waters. Probably the most notable and most toxic coelenterate is the box jellyfish (*Chironex fleckeri*), also known as the “sea wasp.” More dangerous than the famed great white shark, this small animal causes several deaths along the Australian coast annually.\(^9^0\) Cardiac arrest may occur within minutes, and early aggressive resuscitation offers the best chance of recovery. Intravenous verapamil and box jellyfish antivenin are advocated for use in treatment.\(^9^1,9^2\) Another north Australian jellyfish, *Carukia barnesi*, also produces a devastating envenomation known as *Irukandji syndrome*. This causes major catecholamine release, hypertensive crisis, and passive death.\(^9^3\)

The Portuguese man-of-war (*Physalia physalis*) is found along the southern U.S. coastline. This organism is not a true jellyfish but a hydroid colony and is most often included in the jellyfish literature. Envenomation is usually limited to local pain and paresthesias, but it may progress systemically to nausea, headache, chills, and even cardiopulmonary collapse. This organism has also been responsible for several deaths.\(^9^4,9^5\)

Most other envenomations are minimal, and the danger is either drowning after being stung or an allergic reaction to the venom. The symptoms resulting from coelenterate
envenomation usually consist of a severe burning sensation accompanied by raised erythematous lesions where nematocysts have discharged into the skin. The symptoms may progress, depending on the species and the number of nematocysts, to include nausea, vomiting, chest pain, muscle cramps, dyspnea, diarrhea, cough, convulsions, angioedema, and respiratory arrest. The initial pain and redness may last from a few hours to 2 or 3 days, depending on the therapy.

A related type of envenomation is caused by various species of coral, particularly fire coral (*Millepora*). These injuries combine nematocyst envenomation with wound contamination. Animal protein and calcareous material left behind in these wounds cause infection and chronic inflammation.

### Stings

Some marine animals cause a “sting” that is produced by a specialized apparatus that punctures the victim’s skin and then introduces venom. Common examples of this type of animal are sea urchins, cone shells, bristle worms, sea snakes, crown-of-thorns starfish, stingrays, scorpion fish, weever fish, catfish, stonefish, rabbit fish, and zebra fish. Sea urchins, cone shells (*Conus californicus*), catfish, scorpion fish, and stingrays account for most of the venomous marine animal injuries in the United States.96

**Sea Urchins.** Sea urchins belong to the Echinoderm family along with starfish and sea cucumbers. These animals produce injury and envenomation mostly through toxin-coated spines. These spines often break off and introduce calcareous material and debris into the wound, thereby potentiating severe infection. Symptoms most often include severe local burning, pain, and discoloration, but they may progress systemically in some patients. The degree of envenomation is usually related to the number of spines involved and the species of animal encountered.

**Cone Shells.** Cone shells are much more toxic than sea urchins, and some species have been responsible for fatalities in the Indo-Pacific region. The venom apparatus is a tubular gland that connects to several teeth at the end of a retractable proboscis. All envenomations reported have occurred in persons handling the shells. The venom contains several proteins, protein-carbohydrate complexes, and 3-indolyl derivatives that act mainly on skeletal muscle and cause variably spastic and flaccid paralysis.97 Symptoms may or may not include pain, depending on the species. Severe envenomation may cause diplopia, slurred speech, numbness, weakness, paralysis, and respiratory arrest. Onset and regression of symptoms may vary from minutes to days. No antivenin is available for cone shell envenomation.

**Stingray.** The stingray is a member of the shark family. It is a broad, flat fish with a long, whiplike tail that may have one or more stings with barbed ends. They vary in size from a few inches to several feet, and the stings are proportional to the size of the fish. The sting is encased in an integumentary sheath and contains venom glands. Stingrays bury themselves in the sand of shallow water, where they can be easily stepped on. Stingray envenomation usually consists of a severe burning sensation that connects to several teeth at the end of a retractable proboscis. The venom apparatus is a tubular gland that punctures the victim’s skin and then introduces venom. Common examples of this type of animal are sea urchins, cone shells, bristle worms, sea snakes, crown-of-thorns starfish, stingrays, scorpion fish, weever fish, catfish, stonefish, rabbit fish, and zebra fish. Sea urchins, cone shells (*Conus californicus*), catfish, scorpion fish, and stingrays account for most of the venomous marine animal injuries in the United States.96

**Bony Fishes.** Bony fishes inflict their wounds through spines located on their fins. The spines and venom glands are encased in a sheath, and grooves along the spines act as channels for the venom. These fish injuries are typically encountered when the fish are stepped on in shallow water or handled by fishermen. The venom is made up of several classes of proteins, most of which are heat labile. The family Scorpaenidae includes three groups of species categorized by venom apparatus: zebra fish, scorpion fish, and stonefish. Zebra fish include the popular aquarium resident, the lionfish. Scorpion fish produce intense pain that can spread to the entire affected extremity within minutes.98 Stonefish envenomation may cause serious and even life-threatening systemic illness, but manifestations such as cardiac and respiratory symptoms can be prevented by early administration of the appropriate antivenin.21 Saltwater and freshwater catfish produce envenomation through contact with dorsal and pectoral spines.100

### Management

Much of the venom can be neutralized at the scene, and most fatalities can be prevented. The most important step is to remove the victim from the water. Drownings after minimal envenomation may account for more fatalities than the end effects of severe envenomation. The patient should be questioned about the circumstances of the bite, allergies, and systemic symptoms. If a severe allergic reaction has occurred, the victim should be treated for this emergency before attending to the wound. The type of wound care largely varies according to the type of venom apparatus involved. As with all wounds encountered in the emergency department, appropriate cleansing, débridement, and tetanus prophylaxis are paramount. Prophylactic antibiotics such as ciprofloxacin should be given when indicated and when residual foreign body is suspected. Specific antivenins are available for some species, such as the box jellyfish and stonefish.

Bite injuries should be treated with basic life support measures and general wound care consisting of cleansing, débridement, and irrigation. Systemic signs and symptoms are treated accordingly, with aggressive attention paid to the cardiac and respiratory systems.

### Nematocysts

Nematocyst injuries are treated by first removing the nematocysts without allowing them to discharge. Tentacles should be removed with a gloved hand or forceps. The remaining nematocysts should be fixed by pouring vinegar (dilute acetic acid) over the wound area. Baking soda and alcohol have also been shown to be effective, and deactivation of nematocysts may be species specific. Fresh water should not be used because it may stimulate continued nematocyst discharge.101 Other methods include scraping off residual material with the use of a shaving cream or baking soda slurry. The affected area should then be debrided and cleansed. Hot water immersion may relieve pain. Most lifeguard stations in areas where coelenterate stings are common have the necessary materials for this regimen. Supportive pharmacologic therapy (e.g., analgesics, antihistamines, and steroid creams) is indicated for all but the most trivial envenomation. Delayed cutaneous reactions may persist despite optimal therapy.102,103

### Fish

Puncture injuries are treated by removing the spine or sting if possible. An x-ray film should be taken of the involved area because many spines and sheaths are radiopaque. Sea urchin
spines usually break off in the wound; they are so fragile that removing them is difficult without the proper instruments. The sting of the stingray should be removed with forceps, although these stingers with their sheaths have been known to penetrate body cavities and require surgery for removal. Although not usually present in the wound, the fish spines of bony fish should be removed with forceps. In all cases, the wound should be copiously irrigated. Most venoms injected through puncture wounds are heat labile. Significant analgesia can be achieved by submersion of the wound in hot (110°F) water for 30 to 90 minutes or until symptoms improve. Patients envenomed by unknown or unfamiliar organisms should be observed for systemic signs and symptoms. Careful discharge instructions should warn the patient to return for increasing pain, numbness, difficulty breathing, and signs of infection.

INTRODUCTION

Burns are injuries to the skin resulting from contact with heat, electrical current, radiation, or chemical agents. The common denominator in all burns irrespective of the source of the energy is protein denaturation. With thermal burns, the degree of injury sustained is dependent on the amount of heat or temperature, the duration of the exposure, and the intrinsic structure of the burned tissue that determines its heat conductivity. Temperatures less than 44°C can generally be tolerated for prolonged periods without causing burns. As the temperature rises, there is an exponential decrease in the duration of contact required to produce injury, since the proportion of unfolded protein molecules increases dramatically at supra-physiologic temperatures. At temperatures above 60°C, most tissue proteins are denatured. The lipid bilayer and membrane-bound adenosine triphosphatases are the proteins most predisposed to thermal denaturation, and the thermal alteration of the plasma membrane is likely to be the most significant cause of the tissue necrosis.

The young and elderly are more likely to sustain deep burns because their skin is generally thinner than that of adults. The blood supply of the skin may also affect the susceptibility to injury, since blood flow dissipates heat. Epidermal appendages within the dermis (e.g., sebaceous glands and hair follicles) also help to dissipate heat and reduce the degree of injury.

BURN EPIDEMIOLOGY

According to the American Burn Association, 500,000 burn injuries are treated in medical facilities each year. This includes 4000 deaths, which occur mostly in residential fires. Of the 40,000 burn admissions each year, more than 60% are admitted to specialized burn centers. The majority of burns occur from fire/flame (46%), scalds (32%), contact with hot objects (8%), electricity (4%), or chemical agents (3%). Over one third of admissions (38%) exceed 10% total body surface area (TBSA), and 10% exceed 30% TBSA. Most admissions include severe burns of such vital body areas as the face, hands, and feet. The overall survival rate from burns in the years 1995 to 2005 was 94.4%.

The National Center for Health Statistics indicates a decreasing trend in the number of burn visits from 1996 to 2000, with no further changes in trends from 2000 to 2005. Half of patients presenting to the emergency department (ED) were between the ages of 19 and 44 years. The most commonly affected body areas were the upper extremities (41%), lower extremities (26%), and head and neck (17%). Most of the burns were partial-thickness injuries, and less than 5% were full thickness.

BURN PATHOPHYSIOLOGY

Traditionally the burn injury has been divided into three concentric zones. At the center of the burn is a zone of irreversible coagulative necrosis that is formed immediately after injury. Surrounding this central core is a zone of ischemia in which there is a reduction in the dermal microcirculation, putting this area at risk for subsequent necrosis if the perfusion is not improved. The zone of ischemia has been the focus of intense research, which is directed toward reversing or preventing the conversion to necrosis. The third and outermost zone is the zone of hyperemia, characterized by an immediate and transient increase in perfusion. The ability of the skin to regenerate itself without scar formation is highly dependent on the level of injury. Regeneration of the damaged epidermis occurs from two primary sources. The basal layer of cells from the uninjured adjacent epidermis can give rise to re-epithelialization of the burn; however, this is limited to 1 cm from the wound edges. With large burns, the major source of regenerative epidermal cells comes from the dermal skin appendages: hair follicles and sebaceous glands. More damage to the epidermal appendages increases the likelihood that the burn will heal with scar formation.

Injury to the skin results in the activation of a number of complex hematologic cascades, which include the clotting and the complement system, and results in the local activation and recruitment of inflammatory cells such as leukocytes and monocytes to the site of injury. In order to facilitate passage of the inflammatory cells from the systemic circulation through the blood vessels and into the site of injury, glycoproteins known as the β2 integrins, including CD11b and CD18, are expressed on the surface of the neutrophils, allowing them to adhere to the endothelial cells. Administration of monoclonal antibodies aimed against CD18 in an animal model results in a reduced area of burn injury and more rapid healing. Intercellular adhesion molecule-1 is also expressed on the endothelial cell surface, which binds to integrins on leukocytes, allowing them to marginate or adhere to the vessel walls.

Once activated inflammatory cells are in the area of injury, they release a large number of inflammatory mediators or cytokines as well as cytotoxic reactive oxygen and nitrogen species,
which results in lipid peroxidation of cell membranes, damaging their integrity. The accumulation of leukocytes, red blood cells, and platelets in the blood vessels of the injured area results in the formation of microthrombi, which further reduce local perfusion. The extent of the burn injury is often exacerbated by recurring cycles of ischemia and reperfusion that result in increased formation of reactive oxygen species. The presence of prostaglandins, histamine, and bradykinin increases the permeability of the blood vessels, leading to hypoperfusion secondary to edema-related fluid shifts from the intravascular compartment into the interstitial space.

The cytokines released after injury (such as tumor necrosis factor alpha, interleukin-1 [IL-1], and endotoxin) activate nuclear factor kappa beta, which induces the synthesis of inducible nitric oxide synthase, which leads to further production of nitric oxide, an important reactive nitrogen species. Reactive oxygen species result in damage to DNA, proteins, and lipids. Lipid peroxidation is thought to cause oxidative damage to the cellular membrane and eventually result in cell death. Reactive nitrogen species (such as nitric oxide) also inhibit T cells, thus participating in the immunosuppression associated with large burns.

Abnormal and denatured proteins accumulate as a result of exposure to heat, causing a stress response that increases the expression of heat shock proteins. These proteins play an important role in protein assembly, transport, and repair. The production of the heat shock proteins is induced by a number of transcription factors termed heat shock factors, which are activated by the stress response. The heat shock proteins in turn help attenuate the production of proinflammatory cytokines such as tumor necrosis factor alpha, IL-1, and IL-6, which tend to increase the extent of the burn injury.

A predisposition to infection, metabolic derangements, and other factors predispose partial-thickness burns to progress to deeper burns. Lack of adequate fluid resuscitation and hypoperfusion contribute to the deepening of the burn wound. Impaired ability to combat infection is common in patients with large burns and appears to be cytokine mediated. In particular, IL-12 has been shown to depress immune function. Abnormal compliment activity is another factor in large burns that predisposes to infection.

**Pathophysiology of Inhalation Injury**

Injury to the airways can be the direct result of thermal injury from steam or more commonly from the products of incomplete combustion such as the aldehydes and oxides of sulfur and nitrogen. Toxic compounds released from burning of common household materials such as polyvinylchlorides include hydrochloric acid and carbon monoxide. Upper airway obstruction that occurs within the first few hours after injury is generally caused by chemical irritation. In up to one third of burn patients with inhalation injury, acute upper airway obstruction occurs due to the rapid progression of pharyngeal and supraglottic edema.

The upper and lower airway pathology is secondary to airway edema and de-epithelialization of the injured tracheobronchial mucosa, with progressive shedding of the necrotic lining of the airway and the formation of pseudomembranous casts that partially or completely obstruct the airway. These casts consist of necrotic epithelium, mucus, cellular debris, fibrinous exudate, polymorphonuclear leukocytes, and clumps of bacteria. In addition, there may be severe edema and congestion of the pulmonary parenchyma with infiltration of leukocytes that release additional inflammatory mediators and reactive oxygen species that further contribute to bronchospasm, tissue inflammation, and destruction. Damage to the mucociliary function of the endobronchial mucosa reduces the ability to eliminate excess mucus and secretions. The increase in extravascular water content and pulmonary lymph flow causes a marked decrease in the compliance of the lungs. Inhalation injury also results in deactivation of pulmonary surfactant, leading to areas of microatelectasis causing ventilation perfusion mismatch and pulmonary shunting, and results in progressive hypoxemia and ultimately the clinical syndrome of acute respiratory distress syndrome.

### CLASSIFICATION AND DIAGNOSIS OF BURNS

Burns can be classified by mechanism of injury, depth, extent, and associated injuries and comorbidities. Determination of the depth of injury is crucial as appropriate treatment is contingent on the depth of injury. The current burn classification system is several hundred years old and was first described by the French barber surgeon Ambroise Paré. First-degree burns are limited to the epidermis and characterized by erythema and pain. They generally heal within several days to a week. Second-degree, or partial-thickness, burns extend through the epidermis and into the dermis. They may be divided into superficial and deep partial-thickness injuries depending on the depth of dermal injury. Superficial second-degree burns extend into the superficial (papillary) dermis. The skin is erythematous and forms blisters, and the surface can be moist. Deep second-degree burns extend through the epidermis into the deep (reticular) dermis. They appear white with some erythematous areas and exhibit less blanching and moisture than the superficial second-degree burns (Fig. 60-2). The distinction between superficial and deep second-degree burns is important in that deep second-degree burns often do not heal within 2 to 3 weeks and often result in severe scarring and contractures, especially in children. As a result, deep second-degree burns that do not heal within 21 days require excision and skin grafting in order to minimize scarring. Deep second-degree burns may also progress to third-degree burns over the course of several days after injury. Third-degree burns extend through both the epidermis and the entire dermis and are referred to as “full-thickness” burns. Their appearance is stiff and white or tan. They are dry or may have a charred

</table>
appearance (Fig. 60-3). They do not blanch, and due to destruction of the nerves are not painful. Finally, fourth-degree burns extend through the skin and subcutaneous fat into the underlying muscle and bone. Fourth-degree burns are stiff and charred and have visibly thrombosed vessels. Most burns are not uniform in depth and have areas of varying depth of injury.

Clinical estimation of the depth of the burn is often inaccurate. It is particularly difficult to distinguish superficial partial-thickness burns that heal spontaneously from deep partial-thickness injuries that require excision. Many tools exist that help determine burn depth (such as laser Doppler and magnetic resonance imaging); however, these are not generally available in the ED. Clinical examination remains the most frequently used means of diagnosis. Serial assessments are necessary to distinguish between deep and superficial burns as the injury is dynamic and often continues to evolve after initial presentation.

The extent or surface area of the injury must be evaluated. The ability to estimate the percentage of total body surface area burned is often inaccurate on initial inspection. Clinical rules and charts are commonly used for more precise estimation of the percentage of TBSA involved. Careful estimation is critical because the volume of fluid administered is based on this evaluation and an overestimation of the extent of injury can lead to inappropriate fluid administration. In addition, the criteria for referral to a burn unit are dependent on the surface area of the burn. In general, only second- and third-degree burns contribute to the calculation of the percentage of TBSA affected. A useful clinical rule for smaller burns or scattered areas of burn is that the area of a patient’s palm and fingers is approximately equivalent to 1% TBSA. For larger burns, the “rule of nines” is used. This rule states that the allocation of percentage of TBSA in an adult patient can be estimated as follows: 18% for the front and 18% for the back of the trunk, 18% for each lower extremity, 9% for the head and 9% for each upper extremity, and 1% for the perineal area. A Lund-Browder chart is useful for estimating the extent of burns in children (Fig. 60-4). The rule of nines should not be
used for children as their head is larger and their extremities smaller in proportion compared with adults. 38

Finally, burns are classified by severity into minor, moderate, and severe based on the TBSA burned, the percentage of full-thickness injury, and the involvement of specific areas such as the face, hands, feet, or perineum (Table 60-2). In addition, consideration is given to the presence of inhalation injury, high-voltage electric burns, associated major trauma such as fractures, extremes of age, and comorbid conditions.

### MANAGEMENT OF BURNS PRIOR TO ED ARRIVAL

The goal of care before ED arrival is to deliver the burn patient to the hospital in the best possible condition. The first priority is to stop the burning process and to protect the patient from additional injury. If clothing is burning, extinguish the flames with water or smother the flames with a blanket and gently remove the involved clothing. If chemical injury has occurred, immediate and copious dilution of the chemical agent with tap water and prompt removal of all involved clothing are necessary while still protecting those aiding the patient from exposure. After the burning process has been stopped, the priorities of care are assessment of adequacy of airway and ventilation and assessment of the cardiac status and peripheral perfusion. If the patient has a compromised airway, orotracheal intubation should be performed. If the patient is alert and oriented and the areas of unburned skin are warm and dry, it may be assumed that the patient is adequately perfusing his or her vital organs. If there is a suspected inhalation injury or carbon monoxide intoxication, the patient should be placed on 100% oxygen delivered by a non-rebreather mask. The possibility of a concomitant traumatic injury, particularly a cervical spine injury, should be considered and necessary spinal precautions should be addressed. Prehospital infusion of intravenous fluid is beneficial in those patients with extensive burns (greater than 20% TBSA) in whom intravenous access can be established expeditiously. Whenever possible, the intravenous fluid should be initiated through unburned skin. Lactated Ringer’s (LR) solution is the intravenous fluid of choice since it may reduce the risk of hyperchloremic acidosis associated with use of normal saline. The amount of LR solution required for the first hour can be rapidly estimated using the Parkland formula by multiplying the estimated TBSA of the second- and third-degree burn by body weight in kilograms and dividing by 4. When preadmission protocols allow use of opioids, morphine sulfate should be administered intravenously during transport to the hospital using frequent 2- to 4-mg intravenous boluses.

Burns should be covered with a clean dressing. Cooling with tap water or a commercially available cooling blanket 39,40 helps reduce pain. Care should be taken to minimize hypothermia, especially when ambient temperature is low. Topical antimicrobial agents should not be used in the prehospital phase of burn care because they offer few significant benefits during transport and must be removed when the patient arrives at the hospital.

### EMERGENCY DEPARTMENT MANAGEMENT OF BURNS

Severely burned patients are among the most critical patients seen in the ED. Burn injuries are extremely painful and dramatic, and there is a tendency to focus on the burn wounds. However, all burn patients must be approached in a systematic manner focusing on the ABCs first. Some burn patients have associated traumatic injuries or comorbidities that must be identified and addressed.

#### Airway Management

Management of the upper airway in burn patients may be extremely challenging. After exposure to superheated steam and toxic fumes, rapid and progressive upper airway edema may develop within minutes. 31 If there is doubt regarding the presence of upper airway compromise, fiberoptic laryngoscopy should be performed. Endotracheal intubation guided by fiberoptic laryngoscopy/bronchoscopy is a useful technique, and if attempts at intubation are unsuccessful, surgical cricothyotomy or needle cricothyotomy may be necessary. After placing an endotracheal tube, several devices are available to help secure the tube. 42 With circumferential neck burns, the stiff burn eschar may compress the airway (as well as the major neck vessels) and require laterally placed escharotomies on either side of the neck.

#### General Measures for Moderate to Severe Burns

All patients with moderate to severe burns and those with suspected inhalation injury should receive supplemental humidified oxygen to maintain an oxygen saturation greater than 92%. With severe burns, intravenous access should be obtained with at least two large-bore intravenous catheters in peripheral veins, preferably in a noninjured limb. If peripheral access cannot be obtained, central venous access will be required. Patients with severe burns require a urethral catheter to monitor urine output and evaluation for rhabdomyolysis and myoglobinuria. A nasogastric tube should be placed in order to prevent gastric distention that would compromise ventilation. Patients should also have continuous cardiac and oxygen
saturation monitoring, as well as frequent assessment of the arterial blood pressure.

**Recognizing Inhalation Injury**

Smoke inhalation injury affects between 5 and 35% of hospitalized burn patients. With improvements in fluid resuscitation, inhalation injury has become one of the two causes of morbidity and mortality in burn patients. The presence of inhalation injury increases the mortality from burns by 20% and when combined with pneumonia by 60%.

Traditionally, inhalation injury was diagnosed based on clinical findings such as facial burns, singed nasal vibrissae, carbonaceous sputum, and a history of injury within a closed space. However, these findings are neither highly sensitive nor highly specific. Similarly, wheezing, crepitations, hypoxemia, and abnormalities on the initial chest radiograph may or may not be present in the ED, except in the most severely injured.

The diagnosis of inhalation injury in the ED is best made by direct visualization of the airways with fiberoptic laryngoscopy (before intubation) and bronchoscopy (after intubation). Findings of inhalation injury include the presence of soot, charring, and mucosal inflammation, edema, or necrosis. While bronchoscopy is useful in identifying injury to the airway, it cannot exclude parenchymal injury. Diagnosis of injury to the parenchyma of the lung is best made using xenon ventilation scanning, which demonstrates areas of decreased alveolar gas washout secondary to small airway obstruction. However, xenon scanning is rarely, if ever, used in the ED setting.

Carbon monoxide levels should be based on measurement of serum carbon monoxide levels using co-oximetry. Cyanide, a frequent combustion product of plastics, should be suspected in patients in a closed space fire with elevated carbon monoxide and elevated lactate levels.

**Management of Inhalation Injury**

Deciding when mechanical ventilation is required is critical. In addition to securing the upper airway, there are several other indications for endotracheal intubation and mechanical ventilation (Table 60-3). Alveolar lavage may be required to help remove thick secretions and improve pulmonary toilette. This has been simplified by smaller and more flexible bronchoscopes.

There are many modes of mechanical ventilation, each having their own advantages and disadvantages. In the ED most patients who are intubated will require heavy sedation with or without paralysis, and therefore, the assist control mode, in which the ventilator cycles automatically at a preselected rate, is most appropriate. The goals of mechanical ventilation should include achieving an acceptable oxygen saturation (>92%) and limiting the plateau airway pressures to 35 cm H₂O or less to reduce the incidence of barotrauma. This may require allowing the partial pressure of carbon dioxide (PaCO₂) levels to rise to 35 to 55 mm Hg (permissive hypercapnia) as long as the pH remains greater than 7.25. A recent randomized trial found that low tidal volumes (6 mL/kg of predicted weight) reduced mortality. Therefore, starting tidal volumes should be set at 6 to 8 mL/kg of predicted body weight. Larger tidal volumes may be required if oxygenation is not adequate. Positive end expiratory pressure may also help support oxygenation. In order to reduce hyperoxic lung injury, oxygen concentrations should be titrated to the lowest concentrations that maintain adequate oxygenation. A sample of initial ventilator settings is presented in Table 60-4. High-frequency percussive ventilation may be used to obtain adequate oxygenation while minimizing airway pressures. This mode of ventilation administers high-frequency, time-cycled, pressure-limited subtidal volumes, which may reduce the incidence of barotrauma.

Patients with inhalation injury may develop bronchospasm, and therefore bronchodilators should be used in patients with wheezing. Bronchodilators may improve mucociliary function. Frequent airway suctioning and chest physiotherapy are also helpful at removing secretions. Aerosolized N-acetylcysteine with or without aerosolized heparin has also been shown to help break down thick mucous secretions. An example of a treatment protocol for patients with inhalation injury may include 5000 to 10,000 units of heparin and 3 mL of normal saline nebulized every 4 hours, alternating with 3 to 5 mL of 20% N-acetylcysteine.

**Circulation and Fluid Resuscitation**

Fluid resuscitation is one of the most important elements in the treatment of burn patients. Prior to World War II, many burn patients died of hypovolemic shock and renal failure. The first formal fluid resuscitation protocol was developed treating the burns that occurred during the Cocoanut Grove nightclub fire in Boston in 1942. Since then, many fluid resuscitation regimens have been described; however, the Parkland formula described by Baxter remains the most popular.

Burn injury results in the activation of the complement system and the release of a large number of inflammatory mediators such as histamine, prostaglandins, and leukotrienes. These mediators increase the permeability of the local and systemic vasculature, resulting in the extravasation of intravascular fluids and proteins into the interstitial space, contributing to fluid depletion and soft tissue edema. The leakage of plasma proteins during the first 3 to 5 hours reduces the intervascular oncotic pressure and increases the interstitial oncotic pressure, which leads to an increase in edema formation. With large burns, half of the fluid requirements are due to extravasation into unburned areas.

Patients with small burns (less than 20% TBSA in adults and less than 10–15% TBSA in children) can be successfully treated with oral fluids only. With larger burns, intravenous fluid resuscitation is required to restore intravascular volume and prevent the development of hypovolemic shock. One of the oldest controversies in the management of burn patients is the role of colloids for the resuscitation of burn patients. Since capillary leakage of proteins lasts at least 12 to 24 hours after injury, the consensus is that colloids should not be used during the initial fluid resuscitation unless the burn is very deep. A recent systematic review of 23 trials that included 7754 patients concluded that there is no evidence that resuscitation with colloids reduces the risk of death compared with crystalloids in patients with trauma, burns, or following surgery.

In 1968, Baxter reported that resuscitation of dogs with 50% TBSA burns with a volume of LR solution equal to 24% to 32% of their body weight corrected physiologic and metabolic derangements within 24 hours. The results were optimal when half of the volume was administered within the first 8 hours after injury. These findings were then evaluated in 11 patients with burns covering 30 to 85% TBSA, demonstrating that the required fluid volume of LR was between 3.5 and 4.5 mL/kg/%TBSA. These findings led to the Parkland formula that called for a volume of 4 mL/kg/%TBSA of LR to be given over the first 24 hours, with half of the volume given over the first 8 hours. Later studies demonstrated that most adults and children were successfully resuscitated with 24-hour fluid volumes from 3.7 to 4.3 mL/kg/%TBSA. Other fluid resuscitation formulas have been described (Table 60-5); however, the Parkland formula remains the most commonly used.

It is important that all fluid resuscitation formulas should be used as a general guide and that adjustments must be made to maintain adequate tissue and organ perfusion. Thus, burn patients should be resuscitated with only as much fluid as is necessary to maintain organ perfusion. Organ perfusion can be estimated by heart rate, blood pressure, level of consciousness, capillary refill, and a urine output of at least 50 mL/hr in adults or 0.5 to 1.0 mL/hr in children. Certain patient groups may require additional fluid, including patients with inhalation injury, electrical burns, and those in whom resuscitation is delayed. Patients with inhalation injury require 35 to 65% more fluid than patients with similar sized burns without inhalation injury and do not develop pulmonary edema.

A study of transferred burn patients found that smaller burns tended to be overestimated and over-resuscitated, while larger burns tended to be underestimated and under-resuscitated. This further emphasizes the need for careful monitoring of the volume of urinary output and clinical signs of tissue turgor and adequate resuscitation.

In contrast, there have been rising concerns that overly aggressive fluid resuscitation, often termed “fluid creep,” may have adverse outcomes. In a study of 72 patients, increased fluid volumes were associated with pneumonia, sepsis, adult respiratory distress syndrome, multiorgan failure, and death. Patients who receive more fluid than needed are at risk for the abdominal compartment syndrome, which may lead to acute renal failure. Factors associated with fluid creep include a lack of careful, frequent observations by clinicians, increasing use of opioids (termed “opioid creep”), and the emergence of goal-directed resuscitation. While clinicians are often eager to increase fluid administration in patients with poor urine output and unstable vital signs, they are less likely to reduce fluids in patients with adequate or increased urine output. Goal-directed therapy is aimed at achieving supranormal levels of cardiac output, oxygen delivery and/or consumption, and normal acid-base status. In contrast, restoration of normal physiologic and metabolic conditions in severely burned patients generally requires at least 24 to 48 hours to occur, and “pushing” these parameters prematurely may be detrimental. We believe that excessive initial resuscitation should be avoided, and fluid infusions should be adjusted downward to avoid overhydration and subsequent cardiac failure, especially in the elderly.

Children have a larger TBSA relative to weight when compared with adults and therefore have larger fluid requirements. Fluid resuscitation in children is often calculated based on body surface area instead of weight. The Galveston formula is used to calculate resuscitation needs and gives LR 5000 mL/m² TBSA burned + 2000 mL/m² TBSA over the first 24 hours, with half of the volume given over the first 8 hours. The body surface area can be estimated with the Mosteller formula: ([Height (cm) × Weight (kg)]/3600)^1/2. Infants should have dextrose 5% added to their fluids since they lack adequate carbohydrate reserves.

*LR, Ringer’s lactate; TBSA, total body surface area; NS, normal saline.*
All burns are considered contaminated and require thorough cleansing with soap and water. Obvious debris or necrotic tissue should be gently removed. Care of the burn wound generally requires administration of an oral or intravenous analgesic agent. Patients may need a tetanus toxoid booster (dT or aPdT toxoid 0.5 mL IM) with tetanus immune globulin if necessary.

Cooling of the Burn

The benefits of cooling the burn surface have been recognized for many years. There is controversy regarding the best cooling agent and the optimal timing, duration, and temperature of cooling. Classic studies suggest that the optimal cooling temperature is in the range of 10° to 25°C, but cooling of large burns with ice water can result in hypothermia and increased mortality. Venter et al. found that ice water (1°C–8°C) resulted in more necrosis than no cooling at all, and that when tap water at 12°C to 18°C was used, there was the least necrosis and fastest healing. The beneficial effects of cooling were still present when treatment began up to 30 minutes after injury. External cooling with tap water is associated with a reduction in pain and may reduce the progression of tissue necrosis and limit the requirement for skin grafting. If the patient is made comfortable by the cooling, it should be continued until the pain is reduced. Ice and ice water may lead to increased tissue injury and are contraindicated.

Management of Burn Blisters

The management of burn blisters is a controversial topic. Some suggest that the fluid confined by the necrotic skin can lead to a closed space infection, while others have argued that the intact blister creates a moist wound environment that is beneficial to wound healing. In vitro studies show both positive and negative effects of the burn blister fluid; however, clinical studies show that intact blisters heal faster and are less likely to become infected. A porcine study of deep second-degree burns evaluating the effects of debridement demonstrated faster healing, fewer infections, and less scarring when the burn was left intact. There have been no large trials, however, to confirm this. With blisters that have already ruptured, any necrotic epidermis should be gently removed while leaving adherent epidermis intact.

Burn Dressings

The purposes of a burn dressing are to protect the wound, to reduce pain, to absorb wound exudate, and, finally, to reduce evaporative heat loss. The use of systemic antibiotics is not supported in the literature. Local care for first-degree burns is not required other than optional topical anesthetics, aloe vera, and/or topical nonsteroidal anti-inflammatory drugs (NSAIDs). There are two general methods of treating second-degree burns: (1) the open method, which consists of topical antimicrobials; and (2) the closed method, which uses synthetic occlusive dressings.

The open method is most appropriate for contaminated, large burns with large amounts of exudate. Topical antimicrobials should be used until the burn is completely re-epithelialized to prevent bacterial colonization of the wound. The burn is re-epithelialized when there is a pearly opalescent coating and it is dry to the touch. Antimicrobials used for burn dressings include bacitracin, neomycin, mupirocin, silver sulfadiazine, and mafenide. After the antimicrobial is applied, a nonadherent dressing can be used to cover the wound. With this method the dressings should be removed daily and the burns cleansed with water and soap followed by reapplication of the antimicrobial agent and dressing. Traditionally, silver sulfadiazine and mafenide were the mainstays of treatment. However, there are rare adverse reactions. Silver sulfadiazine should not be used in patients with sulfia allergy, and rarely it has also caused reversible bone marrow suppression. Experimentally, silver sulfadiazine has been shown to adversely affect keratinocytes and fibroblasts, and in large burns, mafenide acetate is associated with metabolic acidosis.

The second method of dressing partial-thickness burns is with occlusive dressings. Occlusive dressings support a moist wound healing environment that is optimal for healing. A moist environment has been shown to enhance re-epithelialization and angiogenesis and to reduce pain, partly since these dressings do not need to be changed daily. Occlusive dressings are most appropriate for superficial second-degree burns with little exudate. There are six major types of materials used for occlusive dressings: polyurethane films, hydrocolloids, alginates, silver impregnated dressings, hydrogels, and composites (Table 60-6). The development of products containing nanocrystalline silver has renewed interest since silver has potent antimicrobial properties against both gram-negative and gram-positive organisms as well as fungi such as Candida. Nanocrystalline silver is less rapidly deacti-

vated than the ionic form of silver and thus does not require frequent dressing changes and reapplication. Nanocrystalline silver has been incorporated into many new sustained delivery dressings that have been shown to reduce pain, but also are more cost effective with less frequent dressing changes. Examples of such products include Acticoat (Smith & Nephew, Hull, United Kingdom) and Aquacel Ag (Convatec, Skillman, NJ).

Multiple trials have compared silver sulfadiazine with the newer occlusive dressings for the treatment of partial-thickness injuries. There is faster re-epithelialization, lower cost, and reduced length of hospital stay with burns treated with Aquacel Ag. Absorbptive hydrocolloids (such as DuoDerm [Convatec, Skillman, NJ]) have also been shown to be effective and less painful than traditional silver sulfadiazine. Biosynthetic composite dressings such as biobrane, Apligraft (Organogenesis, Inc., Canton, MA), and transcyte are generally limited to use by burn specialists.

Most patients with minor burns can be treated in the ED and discharged home. If the burn is limited in size and has a blister, the patient should be reexamined within 48 hours by a primary care physician. However, if the burn is extensive, or involves the face or the hands, or appears to be dry and deep, the patient should be referred to a surgeon experienced in the care of burns or a burn center that same day.

Escharotomy

Releasing the constriction of a burn eschar with a scalpel or cautery at the bedside is called an escharotomy. Although infrequently needed in the ED, escharotomy can be a limb- or life-saving procedure. The dead skin hardens and forms an eschar that appears as a hard covering. Patients with a large eschar require careful monitoring, especially those with circumferential burns or extensive burns to the chest or neck, since there is the danger of the development of edema beneath the eschar, which leads to constriction and eventual interruption of arterial inflow. In the chest, the increased pressure impairs respiration. Pain, loss of sensation, and delayed capillary refill may be early signs of reduced perfusion. Traditionally, decreased Doppler signals in the extremity have been used as an indication for escharotomy, but one recent study suggests that pulse oximetry of less than 90% with or without Doppler signals in the involved extremity is an indication for escharotomy. Further, an increase in peak airway pressure or difficulty with ventilation in a mechanically ventilated burn patient may be a sign that escharotomy of the chest is required.

The procedure is performed by making a longitudinal incision down to the fat in the constricting eschar (Fig. 60-5). Care should be taken to avoid underlying vessels and nerves. One study of patients transferred to burn centers found that escharotomy incisions were frequently not made deep enough to relieve the obstruction of flow. It is important to check that an adequate incision has been made by reassessing Doppler signals and pulse oximetry in the extremities and ensuring that the peak airway pressures are decreased after the procedure. Use of cautery to perform escharotomy is preferred by some to minimize bleeding.

PAIN MANAGEMENT

Burns are among the most painful injuries, however, many patients do not receive analgesia while in the ED. In addition to being inhume, inadequate pain management may contribute to an exaggerated inflammatory and stress response, increased pain due to a “wind up” phenomenon, long-term chronic pain and dysesthesias, and the post-traumatic stress disorder. The release of second messenger proteins such as protein kinase C-epsilon and neurotrophins such as nerve growth factor may mediate acute-burn hyperalgesia and priming, resulting in a predilection toward the development of chronic hyperalgesia. Inadequate analgesia may be due to the distraction of the often dramatic burn wound or other associated injuries, or concern that potent analgesics may impair ventilation. Pain management should be of primary concern for all burn patients.

There are three phases of burn recovery, each with a characteristic and different type of pain, and each requiring specific assessment tools and management strategies. These three phases include the emergent or resuscitative phase, the healing phase, and the rehabilitative phase. This chapter will only focus on the emergent phase of pain management.

During the emergent phase of management, patients may suffer from three major types of pain. Background pain describes the underlying pain that results directly from the injury. The amount of background pain is highly variable and also depends on the amount of patient anxiety. This pain is usually described as a continuous sensation of burning or throbbing that exists even when the patient is immobile. Background pain may be substantially reduced simply by covering the burn with a moist cool dressing. Breakthrough pain occurs when the patient experiences a sudden increase in the pain intensity, usually as the analgesic level decreases with time. Shortening of the analgesic dosing interval usually addresses this type of pain. Procedural pain refers to the pain experienced when the burn wound is manipulated or debrided.
This pain is generally very severe but transient in nature. Adding anxiolytic medication to parenteral opioids is useful during this phase of management.94

Nonpharmacologic Methods to Reduce Pain

Cooling of burns with cold water can significantly reduce pain. The optimal cooling temperature is around 10° to 25° C, which is approximately the temperature of tap water.69,70,95 Cooling with ice or ice water increases the severity of injury and should be avoided.96 Cooling is most effective when administered immediately after injury. However, cooling may still be effective up to 30 minutes after injury.90,69 Burns may be cooled by holding the wound under running tap water or by applying moist dressings. Commercially available cooling blankets are also available and are useful, especially in the setting prior to hospitalization.59

Covering the burn with a moist occlusive dressing also reduces pain.82 This effect is probably explained by reducing stimulation of the underlying nerves from air currents and other direct stimuli.

Pharmacologic Therapies

Morphine sulfate and acetaminophen are the most commonly used analgesics in burn patients.97 Minor pain from burns may be managed with oral acetaminophen (1 g in adults or 15 mg/kg in children) every 4 to 6 hours or an NSAID such as ibuprofen (400–800 mg in adults or 10 mg/kg in children) every 6 to 8 hours. The pain of minor burns may also be treated with a topical NSAID or aloe vera.77,98

Moderate to severe burn pain is managed with parenteral opioids (such as morphine sulfate 0.05–0.1 mg/kg) titrated to effect. The intravenous route is recommended due to its rapid and reliable effects and consistent absorption. Due to its short half-life, fentanyl 0.5 to 1.0 µg/kg may be used for managing breakthrough and procedural pain. Intranasal fentanyl at a dose of 1.4 µg/kg may be as effective as oral morphine in both children and adults.59 Intravenous infusion of lidocaine (1 mg/kg bolus followed by 2–4 mg/min infusion) can reduce the severity of pain in burn patients.100,101

Anxiolytics, particularly the benzodiazepines, have been useful adjuncts to pain therapy in burns. Care must be exercised in administering opioids and benzodiazepines together as they may act synergistically to induce hypoventilation and hypotension. Lorazepam (1 mg IV or PO) and midazolam (1 mg IV or intranasally) are both widely used in burn patients.102,103

Other drugs (including gabapentin, stimulants, beta-blockers, and antidepressants) are useful in managing chronic pain and burn pain in the burn unit; however, there is no evidence to support their use in the ED.104,105

■ BURN PREVENTION

The ED visit offers a unique “teachable moment” for physicians to educate patients and their families on preventing burns in the future. Prevention programs and safety legislation have made substantial contributions to decrease the incidence and severity of burn injury, especially for parents or school age children. Areas where burn prevention programs were implemented have a significant decrease in admissions for burn injury.106

In addition, recent initiatives are targeting vulnerable segments of the population for prevention efforts.107,108 Mothers with less than a high school education who are less than 20 years old, and with more than two other children are at much higher risk for a fatal fire event.109 Every visit to the ED provides an opportunity for education. While prevention initiatives are reaching increasing numbers of the population, there is still the need for further education of the public and in particular, those subsegments of the population at high risk for burn injury. Specific recommendations are listed in Table 60-7.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
During the past century, there has been a dramatic increase in the number of chemicals produced. Worldwide, there are at least 5 to 6 million known chemicals, with an additional 10,000 to 20,000 new chemicals developed each year. Furthermore, an estimated 500,000 unique shipments of hazardous materials occur daily throughout the United States, resulting in thousands of exposures to hazardous materials annually. These chemicals, which include acids, alkalis, and other highly reactive substances, not only are found throughout industry but also are ingredients in many household products. Exposure to these substances can result in injuries to many organs, including the eyes, skin, and lungs.

Despite myriad potential exposures to chemicals each day, the number of actual exposures is relatively low, due largely to sound industry practices and state and federal regulations. The Superfund Amendments and Reauthorization Act contains extensive provisions for emergency planning.

The Hazardous Substances Emergency Events Surveillance (HSESS) system collects information on chemical exposures from several states. According to the HSESS database, from 1993 to 2001, the manufacturing sector accounted for nearly half of all chemical exposures in the United States. Transportation, communication, and other public utilities accounted for slightly less than one third of all exposures. Employees working with the chemicals were the most likely to be injured, followed by the general public. Both the current and the past HSESS reports can be found online at http://www.atsdr.cdc.gov/HS/HSEES.

The most commonly released hazardous substances are volatile organic compounds, herbicides, acids, and ammonia. Various household products, such as cement, drain cleaners, and gasoline, are also potentially quite hazardous, and exposure can result in severe disability or death.

Most chemical agents cause skin damage by producing a chemical reaction rather than a hyperthermic injury. Certain chemicals can generate significant heat production following an exothermic reaction. Nonetheless, the majority of dermal injuries result from direct damage to the skin rather than from a hyperthermic injury. The type of chemical reaction produced depends on the properties of the individual agent. In general, however, the degree of damage is directly correlated with the concentration of the toxic agent and the amount of time in contact with the toxic agent. Several other factors also contribute to the degree of injury. Areas of the body where the skin is particularly thin are more at risk than areas of the body where the skin is thicker. In addition, skin that is particularly thin (i.e., elderly skin) or broken (e.g., preexisting abrasions and lacerations) can contribute to more severe injury.

When acidic compounds interact with skin, protein denaturation and coagulative necrosis ensue. This coagulative necrosis produces an eschar, which limits the depth to which the acid can penetrate. Various acids produce characteristic color eschars. For example, nitric acid burns result in a yellow eschar, whereas sulfuric acid burns result in a black or brown eschar. Hydrochloric acid and phenol burns produce a white to gray/brown eschar.

Unlike the coagulative necrosis produced from acids, alkalis produce saponification and liquefactive necrosis of body fat. Because there is no eschar to limit penetration, alkali burns tend to penetrate deeper into the tissues, which results in significant tissue damage.

A hazardous material (HAZMAT) is a substance that can cause physical injury or environmental damage if handled improperly. These substances can be found in residential, urban (e.g., manufacturing), and rural (e.g., agricultural) settings. Furthermore, because these substances are often transported on highways and railroads, a HAZMAT exposure could potentially occur almost anywhere. Nearly three fourths of all HAZMAT incidents involve fixed buildings, whereas the remaining one fourth are transportation-related incidents. Accidents involving fixed locations are most likely to occur during weekdays between 12:00 and 6:00 pm, whereas no time predominance has been shown for transportation-related incidents.

Following a HAZMAT accident, many people may be exposed to the agent. Employees working with the agent are at highest risk of injury, but first responders are also in danger because they frequently arrive before the scene is contained. As a community develops its plans for responding to HAZMAT incidents, it is imperative to know the type of agents that are most likely to be involved.
Identify and Assess Hazardous Environment

The paramedics and members of the HAZMAT response team must work together to identify toxic chemicals and assess hazardous environments. Placards, shipping papers, United Nations chemical identification numbers, and markings on shipping containers help identify the offending agent. In some instances, chemical analysis may be required to assist in the identification of the agent. The presence of carbon monoxide, cyanide, hydrogen sulfide, oxygen, and combustible gases can be detected using different instruments. Calorimetric detector tubes can approximate the concentrations of chemicals in the air. Alpha, beta, and gamma radiation detectors can record radioactive contamination. CHEMTREC (Chemical Transportation Emergency Center) in Arlington, Virginia, maintains a 24-hour telephone hotline (1-800-424-9300) to assist in the rapid identification and management of chemical agents. The staff at CHEMTREC can provide emergency responders in the field with shipper or product information for most chemicals. On average, CHEMTREC handles 22,000 HAZMAT incidents annually.

Contingency Plan

The contingency plan for HAZMAT management can be divided into two parts: initiation of the site plan and evacuation. Initiation of the site plan begins after the specific offending agent has been identified and the surrounding environment has been assessed. Only after the substance has been identified can risks to the public and the environment accurately be identified. A central command post should be used to coordinate the activities of the HAZMAT team with those of the emergency medical services personnel, firefighters, police officers, and other relevant personnel.

Coping with HAZMAT Incidents

When dealing with a HAZMAT incident, two distinct processes must occur simultaneously. First, the scene must be secured, which involves containing the substance, extinguishing fires, and controlling other environmental hazards. All exposed individuals, injured or not, should be decontaminated before they are permitted to leave the scene. In addition, people who are not exposed to the hazardous material must be kept away from the scene to prevent subsequent exposure. Lastly, all injured persons must be treated.

At the outset of any contamination event, the offending agent may not be known. Therefore, first responders and those having direct contact with ill patients must wear personal protective equipment (PPE). Once the first responder is dressed appropriately, decontamination should begin by removing the patient’s contaminated clothing. Dry (anhydrous) chemicals can be brushed off the patient’s skin, followed by copious irrigation with water delivered under low pressure. Liquid chemicals can be copiously irrigated directly. The water used for decontamination should be collected, but decontamination of symptomatic individuals should not be delayed for this process. Ideally, decontamination should occur before arrival in the emergency department (ED). If decontamination has not yet occurred, the patient must be decontaminated prior to entering the ED. The primary and secondary survey can occur simultaneously with decontamination.

Although the exact requirements for PPE among hospital personnel are somewhat controversial, at a minimum, all personnel involved with decontamination should wear chemical-resistant clothing with a hood, boots, eyewear, at least two layers of gloves, and some form of respiratory protection.

MANAGEMENT

The initial management of the chemically burned patient involves removing the individual from the hostile environment. All clothing must be promptly removed and placed in plastic bags, if not already done. Dry chemical agents, such as lye, should be brushed away prior to instituting hydrotherapy. The priority of decontamination should progress from cleaning of contaminated wounds to eyes, mucous membranes, skin, and hair.

Hospital personal involved in decontamination should wear chemical-resistant clothing, with built-in hood and boots, at least two layers of gloves, protective eyewear, and some form of respiratory protection. The minimum level of respiratory protection for hospital personnel during decontamination has not been clearly established.

Chemical burns continue to destroy tissue until the causative agent is inactivated or removed. Therefore, the quicker the agent is removed from the skin, the less severe the injury. Prompt treatment results in a return of the skin pH to normal or near-normal conditions.

Hydrotherapy

Hydrotherapy involves the application of large amounts of water or saline to the affected skin. Gentle irrigation of a large volume of water under low pressure for a prolonged time dilutes the toxic agent and washes it out of the skin. High-pressure irrigation should not be used because it is possible to drive the chemical deeper into the skin. Furthermore, the use of high-pressure irrigation can result in splattering of the chemical into the eyes of the patient or rescuer.

Elemental metals (e.g., sodium) may produce profound exothermic reactions when combined with water. To minimize the exothermic reaction from such compounds, mineral oil should be applied to the skin first, if it is immediately available. However, hydrotherapy should not be delayed while waiting for mineral oil. In addition, some have argued that phenol (carbolic acid) should not be irrigated with water due to concern for enhanced skin penetration after exposure to water. However, use of a substance that has both hydrophobic and hydrophilic properties (i.e., polyethylene glycol) does not demonstrate clear benefit over water alone; therefore, hydrotherapy should not be delayed while waiting for polyethylene glycol.

After exposure to strong alkalis, prolonged hydrotherapy is especially important to limit the severity of the injury. In experimental animal models, the pH of chemically burned skin does not approach a normal concentration unless continuous irrigation has been maintained for more than 1 hour, and the pH often does not return to normal for 12 hours despite hydrotherapy. In contrast, with hydrochloric acid skin burns, the pH usually returns to normal within 2 hours after initiation of hydrotherapy. The mechanism by which NaOH maintains an alkaline pH despite treatment is related to the by-products of its chemical reaction to skin. Alkalis combine with proteins or fats in tissues to form soluble protein complexes or soaps. These complexes permit passage of hydroxyl ions deep into the tissue, limiting their contact with the water diluent on the skin surface. On the other hand, acids do not form complexes, and their free hydrogen ions are easily neutralized.

Water is the agent of choice for decontaminating dermal burns due to either acidic or alkali substances. The deleterious effects of attempting to neutralize acid and alkali burns were first noted in experimental models in 1927. In nearly every instance, animals with either acid or alkali burns that under-
went initial irrigation with water survived longer than animals treated with chemical neutralizers. The striking difference between the results of these two treatment methods is attributed to the additional trauma of the heat generated by the neutralization reaction superimposed on the existing burn. Although the same effect may occur when certain chemicals come in contact with water, large volumes of water tend to limit the exothermic reaction.

However, scientists are beginning to question the belief that neutralization of an alkaline burn of the skin with acid does indeed increase tissue damage because of the exothermic nature of acid-base reactions. Using an animal model with 5% topical acetic acid (i.e., household vinegar), researchers demonstrated that the application of acetic acid to alkaline burns resulted in rapid neutralization of the tissue and reduction of the tissue injury in comparison with water irrigation alone.

**Ocular Injury**

Chemical burns to the eye necessitate emergent management. Alkali burns are more common than acidic burns, and unilateral involvement is more common than bilateral involvement. Common etiologies include inadvertent handling of chemicals with resultant splash injury, exploding batteries, airbag deployment, and intentional assaults. Alkali burns can initially appear trivial, but because of an interaction with lipids in the corneal epithelial cells, a coagulative necrosis results, and deep penetration through the corneal stroma can ensue. The injury can occur rapidly. For example, anhydrous ammonia can penetrate into the anterior chamber in less than 1 minute, resulting in complete blindness.

Similar to cutaneous burns, ocular burns can be classified into four grades, with grade IV being the most severe. Grade I and II burns are associated with hyperemia, conjunctival ecchymosis, and defects in the corneal epithelium. Grade III and IV burns are associated with deeper penetration and, as such, are associated with mydriasis, a gray discoloration of the iris, and rapid cataract formation.

Grade II burns can be differentiated from grade I burns by the hazy appearance of the cornea in the former. Blood vessel thrombosis in the anterior chamber occurs in both grade III and grade IV burns, and as a result limbus ischemia occurs. The degree of ischemia differentiates grade III from grade IV burns: ischemia occurs in less than half of the limbis in grade III, whereas ischemia occurs in more than half of the limbis in grade IV. In addition, grade IV burns are associated with necrosis of the bulbar and tarsal conjunctiva and significant limbal ischemia.

**Treatment**

When a chemical injury to the eye is suspected, copious irrigation should be started immediately. At the scene, the victim should submerge the eyes in running tap water and continuously open and close the eyes. The head should be turned such that the affected eye is lower than the unaffected eye to minimize any contamination into the unaffected eye. In the emergency department, tap water irrigation can be continued while preparing for a more definitive irrigation system. The repeated application of topical anesthetics such as proparacaine can decrease pain and facilitate irrigation. Hydrotherapy can also be accomplished by connecting IV tubing to a bag containing normal saline or lactated Ringer’s solution. The initial therapy should consist of continual irrigation of the eye with 2 L of normal saline during the first 30 minutes. A Morgan lens can be used for irrigation, but there is a theoretical risk of trapping the chemical between the conjunctiva and the Morgan lens, thereby increasing the burn. If a Morgan lens is used, we recommend replacing the lens between saline applications. After 2 L has been infused, litmus paper should be inserted into the conjunctival sac and the pH tested. Irrigation should continue until the pH is at a physiologic level (approximate pH of 7.4). Alkali burns are likely to require more irrigation than are acidic burns. For very severe acid or alkali burns, prolonged irrigation may be needed regardless of a normal ocular pH. It is important to also double-evert the upper eyelid and visually inspect the area for any lodged particulate matter, which may be hidden.

Previously, some experimental settings have found benefit from the application of N-acetylcysteine or cysteine. These collagenase inhibitors are thought to prevent loss of the corneal stroma by limiting the amount of collagenase released from the injured tissue. In one retrospective study, the application of steroids, ascorbate, citrate, and antibiotics resulted in improved outcomes in grade III, but not grade IV, burns compared with steroids and antibiotics alone. It is hypothesized that the citrate suppresses neutrophils and inhibits collagenase, thereby reducing the inflammatory response. Ascorbate has been hypothesized to promote new collagen deposition. Topical antibiotics (e.g., sulfacetamide, gentamicin, and ciprofloxacin) are indicated for any corneal injury. Mobility of the eye should be encouraged to minimize the formation of adhesions (symblepharon). With the exception of the antibiotics, there are insufficient data to recommend using any of the pharmaceutical agents mentioned in this paragraph as part of routine practice.

Immediate ophthalmologic consultation and close follow-up are indicated for all significant exposures. Patients with grade I and II injuries can often be managed as outpatients, but patients with higher-grade injuries should be admitted to the hospital. All but the mildest burns should be treated with a long-acting cycloplegic, a mydriatic. A carbonic anhydrase inhibitor may be used for 2 weeks (or until the pain disappears), after discussion with an ophthalmologist. These medications decrease the potential for pupillary constriction, increased intraocular pressure, and early glaucoma. Procedures such as amniotic membrane patching, anterior chamber paracentesis, and corneal transplant have been used for chemical injuries to the eye, and these are undertaken by the ophthalmologic consultant.

**Hydrofluoric Acid**

Hydrofluoric acid (HF) is an acidic aqueous solution made from the element fluorne. It is commonly used in the petroleum industry to manufacture high-octane gasoline. It is also commonly used in the production of microelectronics and for etching glass, removing rust, and cleaning cement and bricks. Absorption of HF can occur following exposure to the lung, skin, and eyes. In an 11-year review of all HF deaths reported to the Occupational Safety and Health Administration, four deaths resulted strictly from dermal exposure and five deaths resulted from both inhalational and dermal exposure. Several of these deaths were associated with inadequate medical therapy, and all of the cases were associated with unsafe workplace practices.

HF is unique in its mechanism of action. When in a concentrated solution, it can act as a strong proton donor, thereby inducing a coagulative necrosis similar to other strong inorganic acids. However, the free fluoride ion is actually responsible for most of the damage associated with HF exposure. The free fluoride ion scavenges cations, such as calcium and...
magnesium, thereby resulting in systemic hypocalcemia and hypomagnesemia. In addition, the free fluoride ions can inhibit sodium/potassium/ATPase and the Krebs cycle. The combination of cellular destruction and inhibition of sodium/potassium/ATPase can also result in hyperkalemia. The severity of injury depends on the concentration of the substance and the length of exposure.

**Inhalation**

Inhalation of HF is rare, and it almost always occurs in the industrial setting. Patient outcomes vary considerably depending on the concentration and duration of exposure to HF. Inhalation and skin exposure to 70% HF can result in pulmonary edema and death within 2 hours. However, delayed pneumonitis and adult respiratory distress syndrome can also occur, and once symptoms occur, they can be present for months. Pneumonitis can be severe and require ventilatory support.

**Ocular Exposure**

Despite the fact that HF is an acid, exposure of the eye to HF can result in a severe burn with penetration and necrosis of the structures throughout the anterior chamber. As with other ocular injuries, immediate and copious irrigation of the eye is indicated. Systemic absorption is possible.

**Dermal Exposure**

Dermal exposure is perhaps the most common route of injury. Relatively dilute solutions of HF (0.6–12%) are available to the general public in the form of rust removal and aluminum cleaning products. During handling of containers storing HF, contamination of inadequately protected fingers and hands often results in a chemical burn injury. The HF skin burn has a distinct characteristic: the exposure causes progressive tissue destruction. Intense pain may occur quickly or be delayed for several hours, but it can persist for days if untreated. The skin at the site of contact develops a tough coagulated appearance. Eschar formation can occur. If untreated, the burn can progress to an indurated, whitish appearance with vesicle formation in the digits, HF has a predilection for subungual tissue. Vascular compromise can occur, and once symptoms occur, they can be present for months. Pneumonitis can be severe and require ventilatory support.

**Initial Therapy**

The initial treatment of HF skin exposure is immediate irrigation with copious amounts of water for at least 15 to 30 minutes. Most exposures to dilute solutions of HF respond favorably to immediate irrigation. Severe pain or any pain that persists after irrigation denotes a more severe burn that requires detoxification of the fluoride ion. Detoxification is accomplished when an insoluble calcium salt is formed.

All blisters should be removed because necrotic tissue may harbor fluoride ions. The fluoride ions can then be detoxified through topical treatment, local infiltrative therapy, or intra-arterial infusion of calcium. Calcium gluconate (2.5%) gel is the preferred topical agent. However, this gel is often not available in most hospital pharmacies, but it can be made by mixing 3.5 g calcium gluconate powder in 150 mL of a watersoluble lubricant (e.g., glycerin-hydroxyethyl cellulose [K-Y] jelly). The gel should be secured by an occlusive cover (e.g., powder-free latex glove). Because the skin is impermeable to calcium, topical treatment is effective only for mild, superficial burns.

**Infiltration Therapy**

**Subcutaneous.** Infiltrative therapy is necessary to treat deep, painful HF burns. Calcium gluconate is the agent of choice and can be administered by either direct infiltration or intra-arterial injection. A common technique involves injecting 0.5 mL/cm² of 10% calcium gluconate subcutaneously through a 27- or 30-gauge needle. The use of an equal volume mixture of 5% calcium gluconate and 0.9% normal saline has been shown to reduce irritation of tissues and decrease subsequent scarring. Patients treated in this manner should be hospitalized for observation and toxicologic consultation.

Despite its wide acceptance, the infiltration technique has disadvantages, especially when treating digits. A regional nerve block is recommended because the injections may be very painful. Removal of the nail to expose the nail bed is required if subungual tissue is involved. Vascular compromise can occur if excessive fluid is injected into the skin exposure sites, and unbound calcium ions have a direct toxic effect on tissue. Because of these disadvantages with subcutaneous infiltration, intra-arterial infusion of calcium is now recommended in most instances.

**Intra-arterial.** An intra-arterial catheter is placed in an artery close to the site of the HF exposure (e.g., radial, ulnar, or brachial artery). Various dilute solutions of calcium have been used, but perhaps the most commonly used solution is a mixture of 10 mL of solution of 10% calcium gluconate in 40 to 50 mL of normal saline infused over 4 hours. If more than 6 hours has elapsed since the time of HF exposure, tissue necrosis cannot be prevented, even through pain relief can occur up to 24 hours after exposure.

The intra-arterial infusion technique also has potential disadvantages. Arterial spasm or thrombosis may result in significant skin loss. The intra-arterial procedure is more costly because it requires hospitalization for the use of the infusion pump and the monitoring of serum calcium concentrations if repeated infusions are used.

**Systemic Toxicity**

HF binds calcium and magnesium ions with strong affinity. Systemic manifestations of fluoride toxicity are at least partly related to hypocalcemia and include abdominal pain, muscle fasciculations, nausea, seizures, ventricular dysrhythmias, and cardiovascular collapse. Consequently, patients with significant HF exposure should be hospitalized and monitored for cardiac dysrhythmias for 24 to 48 hours. Hypocalcemia can occur after significant exposure to HF and should be corrected with the intravenous administration of a 10% calcium gluconate infusion. Calcium chloride can be used, but requires central access to administer. In addition, fluoride ion accumulation has cardiac and neurotoxic effects. Burns as small as 2.5% of the total body surface area have proven fatal in concentrated HF exposure.

**Formic Acid**

Formic acid is a caustic organic acid used in industry and agriculture. It causes cutaneous injury by inducing a coagulative necrosis. Systemic toxicity occurs after absorption and is manifested by acidosis, hemolysis, and hemoglobinuria. Hemolysis is the result of the direct effect of formic acid on the red blood cells.

Copious wound lavage should be instituted immediately. Acidosis should be treated with sodium bicarbonate. Mannitol may be used to expand plasma volume and promote osmotic diuresis in patients with hemolysis. Exchange transfusion and...
hemodialysis may be needed in patients with severe formic acid poisoning.

Anhydrous Ammonia

Anhydrous ammonia is a colorless, pungent gas used extensively as a fertilizer in the agricultural setting. It can also be used in the manufacture of explosives, petroleum, plastics, and synthetic fibers. In addition, a newer method utilizing anhydrous ammonia has become popular. This method, called the “dry cook” or the “Nazi” method, utilizes anhydrous ammonia as a precursor to methamphetamine. As a result of the use of this new method, there has been an increasing number of anhydrous ammonia burns associated with illicit methamphetamine production. In one study, the incidence of anhydrous ammonia exposure from methamphetamine production was three times greater than that from agricultural production.

The sudden release of liquid ammonia can cause injury through two distinct mechanisms. First, anhydrous ammonia has an extremely low temperature (−33°C) and freezes any tissue it touches. Second, the ammonia vapors readily dissolve in the moisture in skin, eyes, oropharynx, and lungs to form hydroxyl ions that cause chemical burns by liquefaction necrosis, which can result in full-tissue skin loss. The severity of injury is directly related to the concentration and duration of ammonia exposure. In general, acute exposure to anhydrous ammonia produces the greatest injury to the proximal airway rather than the distal airway.

Treatment consists of prompt irrigation of the eyes and skin with water and management of inhalation injury. If necessary, the airway should be secured through standard intubation methods. A large-diameter tube should be used to prevent distal airway obstruction from sloughing of mucosa. After intubation, lower airway injury should be managed with positive end-expiratory pressure ventilation.

Cement

Cement is a solid material composed of salicylates and calcium aluminates. When dry cement is combined with water, hydrolysis occurs, resulting in a solution of basic lime hydrate. This solution has a pH of 10 to 12. As hydrolysis continues, however, the pH can increase up to 14, which is comparable with that of sodium or potassium hydroxide or lye.

There are three types of cement burns. The most common burn is a chemically abrasive form, and heat-related or blast-induced burns can also occur. Heat-related and blast-induced burns are more common in the industrial setting and are associated with severe burns, often involving the respiratory tract.

The treatment of a cement burn should attempt to eliminate the toxic component via hydrotherapy. All clothes should be removed, and copious irrigation should occur. Early excision and grafting are often necessary.

Phenol and Derivatives

Phenols are used industrially as starting materials for many organic polymers and plastics. They are widely used in the agricultural, cosmetic, and medical fields. Because of their antiseptic properties (first appreciated by Lister), they are also used in many commercial germicidal solutions. A number of phenol derivatives (e.g., hexylresorcinol and resorcinol) are more bactericidal than phenol.

Phenol (carbolic acid) is an aromatic acidic alcohol. Both phenol and its derivatives are highly reactive, corrosive poisons that damage cells by inducing cell wall disruption, protein denaturation, and coagulative necrosis. Their characteristic odor usually signals their presence. After penetrating the dermis, phenol produces necrosis of the papillary dermis. This necrotic tissue may temporarily delay its absorption. Therefore, when skin comes in contact with phenol, treatment must be instituted immediately. The exposed area should be irrigated with large volumes of water delivered under low pressure. Because dilute phenol solutions are more rapidly absorbed through skin than concentrated solutions, gentle swabbing of the skin surface with sponges soaked in water should be avoided. Any hair, including a beard or mustache, that has come in contact with a phenol should be removed as soon as possible because the phenol can become trapped in hair.

In animal studies, it was found that exposure to as little as 0.625 mg/kg of phenol could be lethal. Systemic toxicity of phenol primarily affects the central nervous system (CNS) and cardiovascular system. In the CNS, toxicity can manifest as stimulation, lethargy, seizures, or coma. Conduction disturbances can be either tachycardic or bradycardic in nature. Marked hypotension may occur as a result of central vasomotor depression, in addition to a direct toxic effect on the myocardial cells and small blood vessels. Also, hypothermia can result from phenol exposure because the phenols are a powerful antipyretic and thus decrease body temperature. Metabolic acidosis can result from both the direct acidic nature of certain phenols and lactate accumulation as a result of cellular dysfunction in shock.

A number of substituted phenols have unique systemic actions that are distinct from those of other phenols. For example, resorcinol can cause CNS stimulation. Picric acid can cause hemolysis, acute hemorrhagic glomerulonephritis, and acute liver injury.

Dilute solutions of phenol are used by plastic surgeons for chemical face peels. Phenols are usually mixed with water, soap, and croton oil. This solution can produce a partial-thickness burn of a predictable depth in a controlled manner. It has been the standard for many years and is now also being used for skin resurfacing to remove wrinkles, irregular pigmentation, and actinic keratosis. The concentration is kept sufficiently low to reduce the occurrence of systemic complications. Interestingly, higher concentrations of phenol result in a shallower burn depth because of increased coagulation of the keratin, thereby preventing deeper penetration. Histologic studies have demonstrated that 100% concentrations of phenol produce 35 to 50% less penetration than a 50% solution.

The physician performing phenol chemical peels should be concerned about the possibility of rapid phenol absorption. Even in a controlled setting, ventricular dysrhythmias occur as a result of the phenol application.

Polyethylene Glycol Therapy

Experimental studies indicate that water alone is effective in reducing the severity of burns and preventing death in animals with skin exposed to phenol and its derivatives. The most effective treatment is undiluted polyethylene glycol (PEG) of molecular weight 200 to 400 or isopropanol (isopropyl alcohol). Adequate supply of either PEG or isopropanol should be stocked in hospitals located near areas of phenol use, and these can often be found in the chemical section of hospital pharmacies. A quick wipe of the skin with PEG solutions reduces mortality and burn severity in experimental animals. These solutions can be used in phenol burns of the face because they are not irritating to the eyes. Decontamination with water should be performed until a PEG solution is
obtained. Large amounts of water must be used, however, because small amounts are detrimental, enhancing dermal absorption of phenol. Removal of phenol should be undertaken in a well-ventilated room so that hospital personnel are not exposed to high concentrations of phenol fumes.

**Treatment of Systemic Toxicity**

The treatment of systemic symptoms is primarily supportive. Respiratory depression may require ventilatory support. Hypotension should be treated initially with crystalloid fluids. If fluid resuscitation is inadequate, vasopressors might be needed. Metabolic acidosis can be treated with sodium bicarbonate. The alkalinization can also help prevent hemoglobin precipitation in the nephron as a result of hemolysis. Benzodiazepines may be required to treat seizures caused by CNS stimulation.

**White Phosphorus**

White phosphorus is widely used in munitions manufacturing and in civilian settings as an ingredient in fertilizers, rodenticides, and fireworks. It has a relatively low melting point of 44°C (111°F). The autoignition temperature (the temperature at which spontaneous combustion can occur) is 30°C (86°F). When white phosphorus comes in contact with air at temperatures above the autoignition point, the phosphorus will spontaneously oxidize, forming phosphorus pentoxide. Phosphorus pentoxide is very hygroscopic—that is, it has the ability to combine with small amounts of moisture in the air. After combining with water, phosphoric acid is formed. In wounds, oxidation of phosphorus pentoxide will continue until it is debrided, neutralized, or consumed.1

Tissue injury from white phosphorus appears to have both thermal and chemical causes. The corrosive action of the phosphoric acid results in an exothermic reaction, thereby liberating heat and causing a thermal burn. The hygroscopic action of the phosphorus pentoxide, however, is also responsible for causing a chemical burn.1 Ultimately, a profound thermal injury can occur, which frequently results in a partial-thickness or full-thickness burn.

Metabolic derangements can also occur following white phosphorus exposure. Hypocalcemia and hyperphosphatemia can occur. Conduction system disturbances can occur as well, which are at least partially explained by the electrolyte derangement. These electrocardiographic abnormalities include bradycardia, QT prolongation, and ST or T wave abnormalities.1,40 These electrocardiogram changes may explain the sudden early death that occasionally occurs in patients with relatively minor white phosphorus burns.

Following oral ingestion of white phosphorus, three stages of toxicity occur. The first stage is characterized by gastrointestinal tract irritation, including vomiting, abdominal pain, diarrhea, and gastrointestinal bleeding. Hypovolemic shock can result. As many as one third of patients who ingest significant quantities of white phosphorus will die during this stage. The first stage can last 8 to 24 hours. The second stage, which lasts 1 to 3 days, is a latent phase in which symptoms appear to improve. However, the third stage is characterized by multisystem organ failure, including hepatic failure, renal failure, and CNS depression. Renal failure is usually present between days 1 and 4, whereas jaundice typically manifests between days 3 and 5.41

The out-of-hospital management involves the immediate removal of contaminated clothing, followed by submersion of the injured skin in cool water. Warm or hot water should be avoided because white phosphorus becomes liquid at 44°C (111°F). Phosphorus particles should be removed from the victim’s skin and submerged in water. The burned skin should be covered with towels soaked in cool water during transport to the emergency department.

After the patient arrives at the emergency department, the burned skin should be washed copiously with normal saline. Previously, some advocated use of a suspension of 5% sodium bicarbonate, 3% copper sulfate, and 1% hydroxyethyl cellulose. Other similar solutions containing copper sulfate have also been described. The use of 0.9% normal saline solution, however, has demonstrated better effects than copper-containing solutions.42 Although there are some conflicting recommendations in the literature,43 given that saline is probably at least as efficacious as copper sulfate solutions and has less associated toxicity, saline irrigation should be considered the preferred irrigating solution.1,40,44

Phosphorus particles can be identified with either ultraviolet light or copper-containing solutions. When using a Wood’s lamp, the phosphorus will fluoresce under an ultraviolet light.44 Unlike copper-containing solutions, the use of a Wood’s lamp is not associated with any adverse or detrimental effects. The use of the copper-containing solutions causes the phosphorus particles to become coated with black cupric phosphate. These black particles are more easily identified and thus more easily removed. Copper sulfate also decreases the rate of oxidation of the phosphorus particles, thus limiting their damage to the underlying tissue. However, because the blackened particles can still cause tissue damage, they must be removed. If a copper solution is used, after 30 minutes of exposure to the burned skin, the copper-containing solution must be thoroughly washed from the skin, thereby limiting the development of systemic copper toxicity. Systemic copper toxicity manifests with gastrointestinal irritation with bluish discoloration of the emesis, hepatotoxicity, hemolysis, methemoglobinema, CNS depression, hypotension, and cardiovascular collapse. Skin burns can also occur at the site of the copper contact.

After hydrotherapy and treatment of associated electrolyte disturbances, definitive management of the skin burns is accomplished as with any other burn wound. Serum calcium and phosphate levels should be monitored for 24 to 48 hours.43

**Nitrates and Nitrites**

Both nitrates (NO₃⁻) and nitrites (NO₂⁻) are abundant in modern society. Both sodium nitrate and sodium nitrite are used in food preservatives for their antimicrobial effects. Nitrites also have many uses in medicine for their vasodilatory properties. Nitrates are commonly used in electroplating, engraving, and metal casting. Nitrites are also commonly used as fertilizing agents. Exposure to either nitrates or nitrites has been associated with methemoglobinemia.45

Reduced hemoglobin contains four heme groups, each with a ferrous (Fe²⁺) ion. Methemoglobinemia results when the ferrous ion becomes oxidized to the ferric (Fe³⁺) state.46 At physiologic levels, there is usually 1 or 2% methemoglobinemia in circulation at any given time. In nonanemic patients, methemoglobin levels less than 20% can produce cyanosis, but the patients are otherwise usually fairly asymptomatic. Levels greater than 20% are associated with headache, anxiety, dyspnea, and tachycardia. Confusion, lethargy, and acidosis typically occur with methemoglobin levels approaching 40 to 50%. Coma, seizures, hypotension, dysrhythmias, and death occur when levels exceed 70%. The diagnosis of methemoglobinemia should be sought in any cyanotic patient who is unresponsive to oxygen therapy and whose blood appears...
chocolate brown in color. Asymptomatic patients can be treated simply by removing the offending agent. For symptomatic patients without G6PD deficiency, 2 mL/kg of 1% methylene blue can be administered over 3 to 5 minutes. Symptoms typically improve within 20 minutes. Severe cases can be treated with exchange transfusion. Candidates for exchange transfusion include patients with G6PD deficiency with significant toxicity from methemoglobinemia and patients who fail to respond to methylene blue.

Hydrocarbons

Hydrocarbons are a heterogeneous group of organic compounds that are derived from carbon and hydrogen molecules. They have become an integral part of modern society; they are found in fuels, solvents, paints, spray paint and spot removers, dry cleaning solutions, lamp oil, rubber cement, and lubricants. Hydrocarbons can be classified as aromatic, in which the carbon moieties are arranged in a ring, or aliphatic, in which the carbon moieties are arranged in a linear or branched chain. Halogenated hydrocarbons are a subgroup of aromatic hydrocarbons in which one of the hydrogen molecules is substituted with a halogen.

The toxicity of hydrocarbons can affect many different organs, but the lungs are the most commonly affected organ. The toxicity of hydrocarbons is directly related to the volatility and inversely related to the viscosity and surface tension. The primary toxicity from hydrocarbons occurs from aspiration following ingestion. Thus, substances with high volatility, low viscosity, and low surface tension are most likely to be aspirated.

Systemic toxicity from dermal exposure to a hydrocarbon is relatively rare. Significant dermal exposures can result in local pain, erythema, blistering, and local edema. Treatment should involve removal of the patient from the source and removal of any contaminated clothing. Copious irrigation with warm water should be performed, and burns should be managed as with other burns.

Chronic dermal exposure can result in a perioral or perinasal dermatitis with pyoderma. This so-called “huffer’s rash” is primarily seen with recreational abuse. The hydrocarbon inhalant can dry the skin, thereby causing microscopic cracks and allowing bacteria to enter, causing a bacterial superinfection.

Significant toxicity from inhaled (nonaspiration) exposure to hydrocarbons is also unlikely to produce serious effects. Some patients may develop mild headache, dizziness, nausea, or wheezing. These symptoms should be treated by removal of the patient from the contaminated environment and administration of oxygen. Wheezing can be treated with beta-agonists.

Ingestion of hydrocarbons can result in aspiration and systemic toxicity. Following ingestion of hydrocarbons, patients should be monitored for 6 hours. A chest radiograph should be obtained 6 hours postexposure. If there are neither radiographic abnormalities nor clinical findings suggesting aspiration (e.g., coughing, gagging, vomiting, wheezing, tachypnea, or hypoxia), the patient can be discharged home. If any of these symptoms are present, admission is mandatory because a hydrocarbon-induced pneumonitis can occur, resulting in severe difficulties with oxygenation. Endotracheal intubation is often required for severe hypoxia. Neither corticosteroids nor empiric antibiotic administration is indicated. Antibiotics may be warranted, however, if a superimposed bacterial infection develops, which will typically occur several days after the pneumonitis develops.

Tar

BURNS FROM HOT TAR PRESENT A TREATMENT CHALLENGE. WHEN HOT, LIQUEFIED TAR COMES IN CONTACT WITH SKIN, HEAT IS TRANSFERRED AND THERMAL INJURY RESULTS. THE TAR COOLS AND SOLIDIFIES ON THE SKIN, MAKING REMOVAL DIFFICULT. THERE ARE TWO TYPES OF HOT TAR: COAL TAR PITCHES AND PETROLEUM-DERIVED ASPHALTS. BOTH PRODUCTS ARE HEATED TO MAINTAIN A LIQUID FORM. ROOFING TAR NEEDS TO BE HEATED TO TEMPERATURES OF AT LEAST 232° C IN ORDER TO ACHIEVE DESIRABLE VISCOSITIES. DEEPER BURN INJURIES ARE ASSOCIATED WITH BURNS FROM ROOFING ASPHALT.

WHEN HOT TAR TOUCHES SKIN, IT RAPIDLY COOLS, SOLIDIFIES, AND BECOMES ENMESHED IN THE HAIR. IT IS IMPORTANT TO FACILITATE THIS COOLING PROCESS BY ADDING COLD WATER TO THE TAR AT THE SCENE OF THE ACCIDENT. COOLING TAR WITH COLD WATER LIMITS THE AMOUNT OF TISSUE DAMAGE AND PREVENTS THE SPREAD OF TARI. TARI SHOULD BE CONTINUALLY WASHED WITH WATER UNTIL IT HAS COOLED AND HARDENED. AFTER COOLING, THE SKIN SHOULD BE DRIED WITH TOWELS TO PREVENT SYSTEMIC HYPOERTHERMIA.

ADHERENT TARI SHOULD NOT BE REMOVED AT THE SCENE OF THE ACCIDENT. IN THE EMERGENCY DEPARTMENT, DEFINITIVE CARE OF TARI BURN INJURY INVOLVES EARLY REMOVAL OF TARI BECAUSE IT OCCLES INJURED SKIN AND ENCOURAGES BACTERIAL GROWTH. TARI ADHERES TO SKIN BECAUSE IT IS ENMESHED IN THE HAIR, NOT BECAUSE OF A DIRECT BOND BETWEEN EPIDERMIS AND TARI.

SOLVENTS USED TO REMOVE TARI IDEALLY SHOULD HAVE A CLOSE STRUCTURAL AFFINITY TO TARI. BOTH PETROLEUM-BASED AROMATIC HYDROCARBON SOLVENTS AND SURFACE-ACTIVE AGENTS SUCH AS POLOXYETHYLENE SORBITAN (TWEEN 80) AND POLYSORBATE (DE-SOLY-IT) HAVE BEEN USED TO FACILITATE TARI REMOVAL. THESE LATTER TWO AGENTS ARE MORE WATER SOLUBLE AND MAY REMOVE TARI MORE EASILY THAN THE PETROLEUM-BASED PRODUCTS. USE OF THESE SURFACE-ACTIVE AGENTS IS AN EFFECTIVE, SAFE, AND INEXPENSIVE MEANS OF REMOVING TARI FROM SKINS. SUNFLOWER OIL, NISA BABY OIL, MAYONNAISE, AND BUTTER HAVE ALSO BEEN USED TO REMOVE ADHERENT TARI FROM SKIN, REQUIRING 30 TO 90 MINUTES FOR COMPLETE REMOVAL. SUNFLOWER OIL HAS PROVED EFFECTIVE AND SAFE IN REMOVING TARI WITHOUT CAUSING FURTHER SKIN DAMAGE.

ASPHALTS ARE SUSCEPTIBLE TO BOTH AROMATIC (E.G., NAPHTHALENE) AND ALIPHATIC (E.G., HEXADE) HYDROCARBON SOLVENTS, WHEREAS COAL TARS ARE SUSCEPTIBLE ONLY TO AROMATIC HYDROCARBONS. BROAD-SPECTRUM ANTIBIOTIC OINTMENTS CAN BE USED TO BOTH HELP WITH REMOVAL AND TO HELP PREVENT INFECTION. IF USED, THEY MUST BE REMOVED AND A NEW COATING APPLIED EVERY HOUR UNTIL ALL THE TARI IS REMOVED. THIS PROCESS TYPICALLY TAKES 12 TO 48 HOURS. COMMONLY USED ANTIBIOTIC OINTMENTS INCLUDE BACTRACIN (400 µG/G), POLYMIXIN B (5000 U/KG), AND NEOMYCIN (5 MG/G). ANTIBIOTIC OINTMENT HAS BEEN USED SUCCESSFULLY TO REMOVE EVEN TARI LAYED OVER THE CORNEA AND CONJUNCTIVA.

Elemental Metals

The elemental metals, such as lithium, sodium, and potassium, are harmless unless they come in contact with water. When this happens, a violent exothermic reaction occurs, which produces heat, hydrogen gas, and hydroxide. The evolved heat is sufficient to ignite the hydrogen gas, which results in further heat production and thermal burns. The formation of the hydroxide compound may also result in significant chemical injury to tissue. The reaction occurs more rapidly with elemental potassium than with sodium. These deleterious effects of potassium have been attributed to trace amounts of potassium superoxide released on exposure to room air. Water lavage is therefore contraindicated in these circumstances.

In the out-of-hospital setting, only a class D fire extinguisher (containing sodium chloride, sodium carbonate, or graphite...
base) or sand should be used to suppress the flames. Once the flame is extinguished, the metal should be covered with an oil (mineral oil is preferred). The oil will isolate the metal from air and water. The patient should be transported to the emergency department for wound débridement and cleansing. Small pieces of metal that cannot be brushed away should be débrided from the skin. Metal fragments can be placed in mineral oil for safe deposit.

### CHEMICAL TERRORISM

Following the terrorist attack on September 11, 2001, the public has become increasingly aware of this type of attack. Despite being banned by the 1925 Geneva Convention, chemical weapons have been used in both the military and the civilian arenas for many years, including the decades preceding the September 11th attack. In the 1980s, Saddam Hussein’s cousin, Ali Hassan al Majid, also known as “Chemical Ali,” was responsible for attacking up to 30 villages in the Jafati valley with chemical weapons. In 1995, Aum Shinrikyo, a Japanese cult, released VX nerve gas in the Tokyo subway, causing 12 deaths and more than 5000 casualties. As terrorist organizations continue to use nonconventional weapons such as chemical and biologic agents, the civilian medical community needs to better understand their characteristics and pathophysiology.

#### Response

The U.S. government recognizes the emerging threat of terrorism and the potential for terrorist organizations to use nonconventional weapons. In 1997, the U.S. Congress appropriated $52.6 million for the Defense Against Weapons of Mass Destruction Act. Subtitle A of this document established the Domestic Preparedness Program to enhance the government’s capability to respond to terrorist attacks with these weapons. The act also focuses on improving local and state agencies to address these threats and to train communities.

The government’s direct response was delineated by Presidential Decision Directive 39 (PDD-39), signed by President Clinton in 1995. For all cases of domestic terrorism, the Federal Bureau of Investigation is assigned to oversee crisis management and to investigate the case for eventual prosecution. The Federal Emergency Management Agency (FEMA) is to coordinate assistance to state and local governments, provide emergency relief, and protect public health and safety. In March 2003, FEMA joined 22 other federal agencies, programs, and offices to form the Department of Homeland Security. The Office of National Preparedness, a division of FEMA, is currently responsible for ensuring that the nation’s first responders are trained and equipped to deal with weapons of mass destruction.

Appropriate casualty triage remains a critical component when dealing with nonconventional weapons. Triage should be performed by specially trained emergency medical personnel who are familiar with these agents and with the use of PPE. The emergency department could be quickly overwhelmed with masses of non-critically injured survivors. Ideally, triage would be conducted both at the scene of the attack and again at a second point before emergency department arrival.

#### Emergency Department Preparedness

Following a chemical attack, triage should be started outside the emergency department. Appropriate decontamination measures should be performed prior to the patients entering the treatment areas of the emergency department. These steps are critical to ensure that other patients and staff are not secondarily exposed. For those directly handling the casualties, PPE such as a full-face respiratory mask, self-contained breathing apparatus, and impermeable suits should be available. The greatest challenge for emergency departments in caring for these individuals is the sudden increase in patients presenting for treatment. The use and location of decontamination showers should be well known, and negative-flow isolation rooms should be available. In emergency departments with only one or two negative-flow isolation rooms, it is possible to put two patients in the same room if they have both been exposed to the same agent. Otherwise, one of the patients might need to be placed outside but in a well-ventilated area. A surveillance system should be established to identify groups at high risk and to evaluate medical interventions. Many of these agents can cause long-term adverse health outcomes, and registries should be established to facilitate appropriate follow-up.

#### Chemical Agents

Chemical agents can be classified as (1) nerve agents, (2) vesicants, (3) choking agents, or (4) cyanide and related toxins (Table 61-1). The first nerve agent documented was tabun, which was synthesized by German chemist Gerhard Schrader in 1937. Schrader developed tabun (military symbol: GA) while researching new insecticides. The following year, sarin (GB) was created. Other popular nerve agents include soman (GD) and VX. Although nerve agents were stockpiled for use during both World Wars, the first documented use in a war was in the 1980s during the Iran-Iraq War. The largest use of

nerve agents by terrorists was by the Aum Shinrikyo cult of Japan, which produced both VX and sarin.

Vesicants, also known as blistering agents, are a class of drug that produce blisters at the site of contact. Despite their discovery in the 1800s, their introduction to warfare did not occur until the 20th century. Since World War I, however, sulfur mustard (also known as mustard gas, mustard, or CAS No. 505-60-2) has remained a constant threat in modern warfare. Other vesicants include lewisite (dichloro-2-chlorovinylarsine), which is an organic arsenical, and phosgene (dichlorofor-moxime), which is a halogenated oxime. Although phosgene is often listed as a vesicant, technically it is not because its urticarial lesions that develop after contact are not fluid-filled.

Choking agents have been used in both military and civilian settings. Although there are many different agents and uses, the collective term choking agent refers to a chemical that can potentially induce pulmonary edema. Phosgene and chlorine are two agents that were used in World War I. Although chlorine is no longer used as a warfare agent, it is still used widely in the industrial setting. Zinc-containing smoke is another choking agent that is used in conventional warfare. Other agents are used for riot control.

Cyanide agents, such as hydrogen cyanide or sodium azide, are cellular toxins. Cyanide was discovered in the 18th century by the Swedish chemist Carl Wilhelm Scheele. Although Scheele gave no indication of its lethal characteristics, today hydrogen cyanide is one of the most toxic chemicals known, with potential deadly consequences if used by a terrorist organization.

### Nerve Agents

The nerve agents can be classified as either “G” agents or “V” agents. The nerve agents are all derived from phosphoric acid and are volatile liquids at room temperature. As such, they must be aerosolized or evaporated in order to be used as an inhalational weapon. Because the vapors are heavier than air, they tend to remain close to the ground and will travel downwind and downhill. However, various weather conditions, such as wind, can result in unpredictable dispersal.

The nerve agents work by affecting acetylcholine (ACh). ACh receptors are found on the postsynaptic receptor of cholinergic synapses. These receptors can be either nicotinic or muscarinic. Activation of the nicotinic receptors results in depolarization of the postsynaptic neuron or skeletal muscle cell, whereas muscarinic activation affects exocrine glands and smooth muscle, primarily in the CNS. Under normal conditions, the enzyme acetylcholinesterase hydrolyzes ACh in the synapse, thereby inactivating ACh. The primary mechanism of action of the nerve agents is to prevent acetylcholinesterase from hydrolyzing ACh. As a result, ACh accumulates in excess. The effects at the muscarinic receptors include excess secretions and smooth muscle contractions. The mnemonics DUMBELLS (diarrhea, urination, miosis, bronchoconstriction/brochiorrhoea, emesis, lacrimation, and salivation) and SLUDGE (salivation, lacrimation, urination, defecation, and gastrointestinal emesis) are often used to describe these effects. The nicotinic manifestations include muscle fasciculations and weakness. The primary clinical toxic effects are respiratory, however, and treatment should be aimed at correcting these effects.

Victims of dermal exposure should be undressed and thoroughly decontaminated with water using large-volume, low-pressure irrigation. Following decontamination, the initial treatment should be aimed at maintaining an airway and restoring adequate oxygenation and ventilation. If rapid sequence intubation is desired for airway management, the paralytic succinylcholine should be used with great caution because its duration of action will be significantly prolonged since the nerve agent will likely inhibit its breakdown. Atro- pine is a direct-acting antagonist of the muscarinic receptor. It is important to note, however, that because atropine does not work at the nicotinic receptors, all nicotinic effects, including muscle weakness or paralysis, will not be reversed with atro- pine. The initial recommended dose is 2 mg of atropine for adults, although much larger doses will likely be required. The endpoint for stopping atropine administration is not improve- ment in heart rate but, rather, drying of bronchial secretions. Pralidoxime should also be administered to patients with suspected or known ingestion with significant symptoms. The traditional dose of pralidoxime is 600 to 1200 mg intramuscularly. Pawars and colleagues examined a high-dose strategy of pralidoxime for organophosphate poisoning. In their study, all patients received 2 g of pralidoxime intravenously as a loading dose. Patients were then randomized to receive either 1 g (over 1 hour) every 4 hours for a total of 48 hours or a continual infusion of 1 g/hr for 48 hours. The continual infusion strategy had lower morbidity and mortality compared with the inter- mittent bolus group. Lastly, benzodiazepines should be given both to prevent and to treat any seizure activity. Exact dosing and treatment strategies should be discussed with a medical toxicologist.

For pediatric patients, if accurate weight-based dosing is not available, children younger than 1 year can receive 0.5 mg atropine, whereas children older than 1 year can receive the standard adult dose of 2 mg atropine as a starting dose.

### Vesicants

At temperatures below 14°C, mustard exists in the solid form. Once in the liquid or gaseous form, mustard gas can be recognized by its unique garlic or fishlike odor. Mustard vapor is also much heavier than air and, as a result, tends to remain close to the ground. When stored as an oil-based liquid, it can be readily aerosolized and attached to a bomb or shell. Because vaporization occurs slowly, the risk of injury is much greater in cool environments and closed spaces. Several minutes of exposure can result in skin and eye injury, whereas exposure for more than 30 minutes can lead to respiratory injury and death.

Mustard gas can enter the body following inhalational, dermal, or oral exposures. After entering the body, it functions as an alkylating agent. The altered molecules then interact with proteins and nucleic acids, forming covalent bonds. Mustard is the only vesicant that does not cause immediate pain. Several hours after exposure, manifestations of exposure occur. Following exposure to aerosolized mustard gas, cutaneous manifestations appear after a latent period of up to 24 hours. Initial dermal symptoms include burning, itching, and erythema, followed by hyperpigmentation, vesicle formation, and, later, bullae. Electrolyte depletion and secondary bacterial infection can occur if the affected body surface area is large. In addition, inhaled mustard gas can lead to vomiting and diarrhea. Myelosuppression can occur within 3 to 5 days of exposure, resulting in leukopenia and thrombocytopenia. Direct mucosal damage in the respiratory tract can occur, resulting in bronchiolar damage and hemorrhage. The systemic manifestations can occur with any route of exposure.

Treatment consists first and foremost of removing the patient from the environment and decontamination of the vesicant. Water can be used for decontamination if that is all
PART II ■ Trauma

Section Four

Choking Agents

Chlorine (CL) and phosgene (CG) were both used in World War I as part of chemical warfare. However, most contact with choking agents today comes from accidental industrial exposures to chlorine. Phosgene is still used in the production of polyurethanes. In addition, riot control agents, such as pepper spray and tear gas, can be considered choking agents. Chemicals are collectively considered choking agents if they induce the sensation of choking and have the potential to induce upper airway damage and pulmonary edema.

Chlorine is a heavy greenish-yellow gas or liquid with a characteristic odor. Today, chlorine is used for plastic production (mostly for polyvinyl chloride), dry cleaning, pharmaceuticals, textile or paper bleaching, water purification, and as a disinfectant. The clinical effects observed following chlorine exposure are directly related to the time and concentration of the exposure. Mild exposure may simply cause nasal irritation, whereas more severe chlorine exposure will induce edema of both the upper airway and the lung parenchyma. In large doses, this edema results in cellular exudates, pulmonary congestion, and hemorrhage. In addition, increased secretions, a sensation of coughing, dyspnea, and chest tightness can be observed. Because chlorine is primarily reactive only at a local level, absorbed systemic effects are not commonly observed.

In contrast to chlorine, phosgene is much less water soluble. As a result, there is less upper airway edema but more alveolar damage, resulting in more severe noncardiogenic pulmonary edema.

The first step in treating an exposure to any choking agent is to remove the individual from the environment. No specific antidote exists, and supportive care is indicated. Following significant exposure to these agents, the ABCs (Airway Breathing and Circulation) should be assessed, with particular attention paid to ensuring an adequate airway and oxygenation. Endotracheal intubation may be required. Any bronchospasm can be treated with beta-agonists such as albuterol. Irritation of the eyes can be handled with copious irrigation of water or saline, and the cornea should be examined for any abrasions.

Cyanide

Cyanide salts and hydrocyanic acid are commonly used for metal cleaning, precious metal extraction, photographic processes, electroplating, laboratory assays, and jewelry cleaning. In addition, cyanide gas is often liberated from the combustion of plastic-containing compounds. There is considerable concern that cyanide can be used by terrorists as a weapon.

Cyanide is considered a cellular toxin. It binds to both Fe3+ and cobalt. By binding and inactivating the enzyme cytochrome oxidase, which is part of cytochrome a3 on the electron transport chain, cyanide inhibits oxidative phosphorylation. This inhibition results in profound cellular hypoxia and death.

Following ingestion of cyanide, many patients will experience sudden cardiovascular collapse. Hypotension and altered mental status can frequently be observed. A characteristic odor of bitter almonds may be noted.

Although cyanide levels can be confirmatory, they are rarely immediately available. However, most patients with significant cyanide exposure will have a profound lactic acidosis. In addition, because the cellular utilization of oxygen is blocked, venous blood is highly oxygenated. As such, an elevated mixed venous oxygen saturation, or an elevated peripheral venous partial pressure of oxygen (PvO2) may be observed. In these cases, the pulse oximeter reading may be near normal, despite significant cellular hypoxia.

A diagnosis of cyanide poisoning requires careful consideration. The initial treatment should be focused on maintaining the ABCs. Standard antiarrhythmic medications are appropriate for the treatment of cyanide-induced arrhythmias. Vasopressors may be required.

Any potentially exposed skin or eyes require prompt decontamination by copious irrigation with saline or water. Currently, two specific types of antidotes can be used to treat known or suspected cyanide intoxication. One method of treatment involves the administration of amyl nitrite, sodium nitrite, and sodium thiocyanate. Using this combination of medications, amyl nitrite pears should be broken open and the patient allowed to breathe a pearl for 30 seconds of each minute. A new pearl is needed every 3 or 4 minutes. Once intravenous access has been established, 300 mg of sodium nitrite (one 10-mL ampule of 3% solution for adults and 0.12–0.33 mL/kg for pediatrics) can be administered. Because sodium nitrite is a potent vasodilator, hypotension can ensue. Thus, the sodium nitrite should be administered over a minimum of 5 minutes. Following sodium nitrite administration, sodium thiocyanate should be administered at a dose of 12.5 g (one 50-mL ampule of a 25% solution for adults and 1.65 mL/kg for pediatrics). The function of the thiocyanates is to induce methemoglobinemia. Thus, in patients who have a suspected simultaneous intoxication of cyanide and carbon monoxide, the thiocyanates should not be used.

In December 2006, the Food and Drug Administration approved hydroxocobalamin (Cyanokit) for treatment of cyanide intoxication. Hydroxocobalamin binds to cyanide to form cyancobalamin, which subsequently undergoes renal excretion. Hydroxocobalamin appears to be safe for use in both the hospital and the out-of-hospital setting, although there may be a reddish discoloration of the skin. In addition, its use is associated with alteration in laboratory measurements of magnesium, iron, aspartate aminotransferase, total bilirubin, and creatinine. If treating a patient for known or suspected cyanide toxicity, either the Taylor Kit (amyl nitrite, sodium nitrite, and sodium thiocyanate) or the Cyanokit (hydroxocobalamin) should be used, but not both.

Acknowledgments

The authors acknowledge the contributions of Richard F. Edlich, Marcus L. Martin, and William L. Long III, who wrote the chapter on chemical injuries for the previous edition.
For chemical injury, the degree of skin destruction is determined mainly by the concentration of the toxic agent and the duration of its contact.

Chemical injuries are commonly encountered after exposures to acids and alkalis.

HAZMATs are substances that can cause physical injury and damage the environment if improperly handled.

In dealing with HAZMAT incidents, two distinct goals must be achieved: (1) The HAZMAT must be contained, fire and explosions must be extinguished, and the site must eventually be cleaned, and (2) people exposed to the HAZMAT must be treated.

For more than 30 years, CHEMTREC has provided crucial information needed to assist emergency response personnel in handling HAZMAT incidents in the safest possible manner.

Alkali burns tend to penetrate deeper than acidic burns; as a result, alkali burns tend to be associated with greater morbidity.

HF burns can be associated with significant hypocalcemia.

Nonconventional chemical weapons may be categorized into four major classifications: nerve agents, vesicants, choking agents, and cyanide agents.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Clinical forensic medicine is the application of forensic medical knowledge and techniques to live patients in a clinical setting. European and British physicians—known as police surgeons, forensic physicians, forensic medical examiners, or forensic medical officers—have performed clinical forensic examinations for more than 200 years, including evaluations on prisoners and victims of physical and sexual assault.

All patients who are victims of physical or sexual assault, abuse, trauma, or a terrorist event have forensic needs. When treating injuries without considering the forensic issues, physicians may misinterpret wounds, miss victims of abuse or domestic violence, and inadequately document the nature of injuries. During the provision of patient care, evidence that can be of critical significance to criminal or civil proceedings can be lost, discarded, or inadvertently washed away. Wound evaluation and evidence collection are critical for victims of a terrorist incident. Their wounds may contain radioactive materials, trace evidence, or bomb fragments that will be an important component of the criminal investigation.

In 1991, the University of Louisville School of Medicine and the Kentucky Medical Examiner’s Office established a clinical forensic medicine training and consultative program in the United States. In 2006, the American College of Emergency Physicians established the Forensic Medicine Section to provide additional forensic resources and training and to include forensic training within residency programs.

Forensic examinations are conducted with the consent of the patient, legal guardian, or court, or by implied consent. The evaluation includes a history and physical examination, photographs, and anatomic diagrams. Evidentiary material, including clothing, hair, blood, saliva, bullets, and bomb fragments is collected when indicated or when ordered by the court. If a patient has been admitted from the emergency department to surgery, an evaluation is done in the operating room. If a patient has been admitted from the emergency department to surgery, an evaluation is done in the operating room.

Errors of Interpretation and Terminology

The emergency physician is in the ideal position to evaluate and document the state of a gunshot wound before it is disturbed, distorted, or destroyed by surgical intervention. Documentation of gunshot wounds should include the anatomic location, size, shape, and characteristics of the wound. Wounds should be described according to the standard anatomic position with the arms to the side and palms up.

Clinicians should not describe wounds as “entrance” or “exit” but should document a detailed description, using appropriate forensic terminology, of the appearance, characteristics, and location of a wound without speculating on an interpretation or the caliber of the bullet (projectile). Exit wounds are not always larger than entrance wounds, and wound size does not correspond to bullet caliber.

The size of any wound (entrance or exit) is determined by five factors: the size, shape, configuration, and velocity of the projectile at the instant of impact with tissue and the physical characteristics of the impacted tissue. If the projectile is slowed and its shape unchanged on exiting the skin, the exit wound may be the same size as or smaller than its corresponding entrance wound. If the projectile increases its surface area by fragmenting or changing its configuration while maintaining a substantial velocity, the exit wound may be significantly larger than the entrance wound.
fragments may extrude from the exit wound and contribute to the size and shape of the wound. Tissue elasticity also affects the wound size so that entrance or exit wound size may be smaller, equal to, or larger than the projectile that caused it.\textsuperscript{15,34-36} Palmar or solar wounds may appear as slits and are easily mistaken for stab wounds.\textsuperscript{28,35,36}

Inappropriate terminology should not be used to describe wounds.\textsuperscript{7,37} An example is the use of the obsolete term powder burns, rather than soot, to describe the carbonaceous material associated with close-range wounds.\textsuperscript{26,29,35,36} Powder burns are literally the burns associated with flaming black powder used in muzzle loaders, antique weapons, and blank cartridges. This does not occur with the smokeless powder used in modern ammunition.

It is unnecessary to document in the medical record the manner of a gunshot victim’s death. The determination of whether a death is accidental, suicidal, or homicidal is the responsibility of the coroner or medical examiner and only after a detailed investigation of the scene and circumstances of the incident. The patient’s position at the time of injury can be determined only after an examination of the scene and collection of all forensic evidence.

A treating physician may be requested to render “factual” testimony, “expert” testimony, or both in a criminal case. Expert forensic testimony not based in science and rendered without an appropriate forensic examination or adequate forensic training may mislead the criminal justice system (e.g., “the exit wound is always larger than the entrance”). Opinions related to entrance versus exit or the range of fire can affect the determination of innocence or guilt.\textsuperscript{15,20,21,23,24,35} The speculation about the wounds in the assassination of President Kennedy is one example of the legal implications of forensic training.\textsuperscript{23,24,38}

**Forensic Aspects of Handguns**

**The Weapon**

There are four categories of handguns: (1) the single shot weapon (usually a target pistol); (2) the derringer (a small, concealable weapon, usually with two barrels); (3) the revolver (a weapon with a rotating cylinder that advances with the pull of the trigger); and (4) the autoloading or semiautomatic pistol (which fires with each pull of the trigger), which is the most popular because the magazine, or clip, can hold up to 17 cartridges compared to the 5 or 6 cartridges for revolvers.

An automatic submachine gun fires pistol ammunition as long as the trigger is held until its ammunition is exhausted. A submachine gun’s magazine may hold up to 60 cartridges. Weapons such as the Israeli Uzi and the Heckler & Koch MP-5 use 9-mm or 40-caliber ammunition and are commonly used by police Special Weapons and Tactics (SWAT) teams. Semiautomatic versions of the submachine gun are available to the general public, and kits to make these weapons fully automatic, although illegal, are sold through gun magazines.

**Handgun Ammunition**

The cartridge, or round, is composed of the primer, the cartridge case, the powder, and the bullet (Fig. 62-1). The bullet is the projectile that is propelled out of the muzzle.

The primer is a small explosive charge in the base of the cartridge that ignites the gunpowder. The primer may contain lead, barium, or antimony, which may be deposited on the hands of the shooter, on the victim of a close-range assault, and on objects within a room in which the weapon is discharged.

The cartridge case is typically made of brass, although other materials may be used. The function of the cartridge case is to slightly expand and seal the chamber against the escaping gases.\textsuperscript{38} On detonation, a cartridge case is imprinted with unique microscopic marks that are valuable evidence and should be preserved for law enforcement.

The gunpowder found in all commercial cartridges except blanks is smokeless powder made with a single base (nitrocellulose) or a double base (nitrocellulose and nitroglycerine).\textsuperscript{38} When a weapon is discharged, not all of the gunpowder is consumed. A percentage of the unburned gunpowder will travel out of the end of the muzzle for a distance, depending on the physical characteristics of the powder.

Blank cartridges, muzzleloaders, and other antiques or replicas may use black powder. Black powder (a combination of potassium nitrate, charcoal, and sulfur) does not burn as efficiently as the smokeless powder and results in a large flame and white smoke.

The bullet is forced from the muzzle of a handgun at velocities ranging from 700 to 1600 feet/second (in magnum loads). The term \textit{magnum} indicates that additional gunpowder has been added to the cartridge case, increasing the velocity of the projectile. The most common bullet types include the round nose, the full metal jacket, the hollow point, the wadcutter, and the semi-wadcutter. Bullets generally have a solid core of lead or steel and have a jacket if the bullet core is covered with a metal, usually copper or aluminum. If the jacket stays with the entire projectile, it is called a full metal jacket, and if the jacket leaves some portion of the core exposed, it is semijacketed.

The term \textit{hollow point} denotes a hole in the tip of the bullet that causes expansion on contact with tissue, which increases tissue damage due to an increased surface area.

Bullet caliber is described in hundredths of an inch or in millimeters. Handgun bullets range from the .22 caliber or 5.56 mm to the .45 caliber or 11.3 mm. A bullet’s weight is measured in grains, with 7000 grains/pound.

**Handgun Wound Ballistics**

Wound ballistics is the study of the effects of penetrating projectiles on the body.\textsuperscript{15,39,40} Many misconceptions surround the science of wound ballistics.\textsuperscript{15,40-44}

Wound severity is directly related to the amount of kinetic energy transferred to the tissue and direct tissue damage, not to the total amount of kinetic energy possessed by the
Bullets fired from rifles generally have a higher velocity—1500 to 4000 feet/second versus 700 to 1600 feet/second in handguns. Therefore, rifled bullets have more kinetic energy and a theoretically higher wounding potential, but wound severity is the result of many variables, such as bullet velocity, weight, deformation, fragmentation on impact with tissue, and the characteristics and location of the impacted tissue.\textsuperscript{32,37,39,40}

The principal mechanism for tissue damage is by crushing. A bullet traveling through tissue generates two cavities, one permanent and the other temporary. The temporary cavity, a result of tissue stretching, lasts 5 to 10 milliseconds from its generation until its collapse and leaves behind the permanently crushed tissue and the permanent cavity.\textsuperscript{33,35,39} The size of the permanent cavity varies with the size, shape, and configuration of the bullet. A hollow-point bullet that mushrooms can increase its diameter 2.5 times on impact and will increase the area of tissue crush 6.25 times compared with a nondeformed bullet.\textsuperscript{35}

The Forensic Evaluation of Handgun Wounds

Entrance Wounds

Range of fire is the distance from the muzzle to the victim and can be divided into four general categories: contact, near-contact or close range, intermediate or medium range, and indeterminate or distant range (Table 62-1). The size of the entrance wound does not correlate with the caliber of the bullet\textsuperscript{15,34,35} because the entrance wounds over elastic tissue will contract around the tissue defect and have a diameter much less than the caliber of the bullet.\textsuperscript{28,35}

**Contact Wounds.** In contact wounds, the barrel or muzzle is in actual contact with the skin or clothing. With tight contact, the muzzle is pushed hard against the skin, whereas with loose contact, the muzzle is incompletely or loosely held against the skin or clothing.

In a tight contact wound, all material—the bullet, gases, soot, the incompletely burned pieces of gunpowder, and metal fragments—is driven into the wound. These wounds can vary from a small hole with seared blackened edges from the discharge of hot gases and an actual flame to a gaping stellate wound (Fig. 62-2). Large wounds occur when the wound is

Figure 62-2. A, Tight-contact entrance wound from a .38-caliber revolver. The wound margins are seared from the discharge of hot gases and an actual flame from the end of the barrel. The triangular-shaped tear is the result of tissue expansion from the discharge of gases into the tissue. B, Tight-contact entrance wound with large stellate tears from a .380 semiautomatic pistol. The large triangular-shaped tears are the result of rapid expansion of gases under the skin. C, Tangential-contact wound from a 9-mm pistol on the medial aspect of the left calf. The presence of soot at the superior aspect indicates a close range of fire. The patient initially reported that he was shot from a distance of 3 or 4 feet and later admitted that he accidentally shot himself while withdrawing his pistol from his boot. Large wounds as seen in B and C may be misinterpreted as exit wounds because of their size.
inflicted over thin or bony tissue, and the injected hot gases cause the skin to expand until it stretches and tears. These tears will have a triangular shape, with the base of the triangle overlying the entrance wound. Tears are generally associated with .32 caliber or greater, or magnum loads. Large stellate contact wounds are easily misinterpreted as exit wounds if based solely on their size (see Fig. 62-2B and C).\textsuperscript{15,28,35}

Stellate tears are not pathognomonic for contact wounds, however. Tangential wounds, ricochet or tumbling bullets, and some exit wounds may also be stellate, but these differ from a tight contact wound by the absence of soot and powder within the wound and a lack of seared wound margins.\textsuperscript{15,28,35,36}

In some tight contact wounds, expanding skin is forced back against the muzzle of the gun, leaving a characteristic muzzle contusion (Fig. 62-3).\textsuperscript{15,28,35,36} Patterns such as these should be documented before wound débridement or surgery because they are helpful in determining the type of weapon (revolver or semiautomatic).\textsuperscript{15,20}

When a gun’s muzzle or barrel is in loose contact or is angled to the skin, the soot and gunpowder residues are present both within and surrounding the wound. The angle between the muzzle and the skin determines the soot pattern. A tangential, loose, or near-contact wound produces an elongated searing and soot deposit surrounding the wound.

\textbf{Close-Range Wounds.} Close range is the maximum range at which soot is deposited on the wound or clothing, usually with a muzzle-to-target distance of less than 6 inches but as far away as 12 inches.\textsuperscript{34,35} Beyond 6 inches, the soot usually falls away and does not reach the target. The concentration of the soot varies inversely with the muzzle-to-target distance and is influenced by the type of gunpowder and ammunition, the barrel length, and the caliber and type of weapon (Fig. 62-4).

A precise range of fire (e.g., 1 cm vs. 10 cm) cannot be determined from examining the wound. A forensic crime laboratory can attempt to reproduce the patient’s soot pattern on a target by test-firing the offending weapon at different ranges using ammunition similar to that which caused the wound (Fig. 62-5). The accuracy of this test depends on an exact and detailed description of the patient’s soot pattern. Because soot can be removed with débridement or wound cleansing, its presence and configuration around the wound should be noted and photographed unless the patient’s clinical condition precludes this attention to detail.\textsuperscript{15,20}

\textbf{Intermediate-Range Wounds.} “Tattooing,” or “stippling,” is pathognomonic for an intermediate-range gunshot wound. It appears as punctate abrasions and is caused by contact with partially burned and wholly unburned pieces of gunpowder (Fig. 62-6). Tattooing or stippling cannot be wiped away. Tattooing rarely occurs on the palms of hands or soles of feet because of the thickness of the epithelium.\textsuperscript{35}

Tattooing may occur as close as 1 cm and as far away as 1 m from the weapon but is generally found at distances of 60 cm or less.\textsuperscript{34,36,45} The density of the tattooing and the associated pattern depend on the length of the barrel, the muzzle-to-skin distance, the type of gunpowder, the presence of intermediate objects, and the caliber and type of ammunition. Clothing, hair, or other intermediate barriers may prevent tattooing from occurring. The presence of partially or entirely unburned pieces of gunpowder and gunpowder residues on clothing or skin aids in determining the range of fire. If gunpowder penetrates even thin clothing, it will generally lack the energy to penetrate the skin.

\textbf{Distant-Range Wounds.} The distant or long-range wound is inflicted from far enough away that only the bullet makes contact with the skin. There is no tattooing or soot. As the bullet penetrates the skin, the skin is indented, resulting in the creation of an “abrasion collar,” also called an “abrasion margin,” “abrasion rim,” or “abrasion ring” (Fig. 62-7). This collar is an abraded area of tissue that surrounds an entry wound, the result of friction between the bullet and the epithelium. The width of the abrasion collar varies with the angle of impact. Most entrance wounds will have an abrasion collar. Entrance wounds on the palms and soles are exceptions because they usually appearing slitlike.\textsuperscript{35}

The abrasion collar is not the result of thermal changes associated with a hot projectile. The edges of a contact or close-range wound may be seared by the release of hot gases and flame. This clinical finding may overlap or obscure the abrasion collar. When an abrasion collar is the only superficial clinical finding present, indeterminate range describes the range of fire. A wound from 10 feet will appear the same as a wound inflicted from 100 feet. An exact range cannot be determined with a distant wound.

Determining the range of fire may be complicated by clothing that prevents the deposition of soot and powder on the skin. When such a wound is examined without the overlying clothing or without information regarding the crime scene, the wound may appear to be from a distant range of fire. In reality, the range may have been close or intermediate. Conversely, a projectile discharged from a distant range of fire may mimic an intermediate range if it strikes an object, such as glass, which fragments. As with unburned gunpowder, when the
Gunshot residue testing conducted at 6 inches with a .32-caliber revolver. The testing searches for the presence of soot (burning of gunpowder), nitrates (unburned gunpowder), and vaporized lead residue. These tests determine the range of fire from the barrel to the clothing. 

"Tattooing" results from contact with pieces of unburned gunpowder. These punctate abrasions are associated with an intermediate range of fire, generally less than 36 inches. The density of these abrasions depends on the length of the gun's barrel, the distance from the muzzle to the skin, the type of gunpowder used, and the presence of any intervening objects.

"Tattooing" or "tattooing" is the result of contact with pieces of unburned gunpowder, leading to punctate abrasions associated with an intermediate range of fire, less than 36 inches. The density of these abrasions is influenced by the length of the gun's barrel, distance from the muzzle to the skin, type of gunpowder, and presence of intervening objects.

Atypical Entrance Wounds. Atypical entrance wounds are indicative of a bullet having encountered an intermediate object, such as a window, wall, or door, before striking the victim. The intermediate object may change the bullet's size, shape, or path. Such changes can result in entrance wounds with large stellate configurations that mimic close-range or contact wounds. Ricochet bullets may also present with atypical entrance wounds.

Graze wounds are atypical wounds from tangential contact with a passing bullet. Directionality of the bullet may be determined from a close examination of the wound. The bullet produces a trough with formation of skin tags on the lateral wound margins. The bases of these skin tags, when present, point toward the weapon and away from the direction of bullet travel.

Exit Wounds

Exit wounds are the result of a bullet pushing and stretching the skin from inside out. The skin edges generally are everted with sharp but irregular margins. Abrasion collars, soot, and tattooing are never seen.
nition, but their wounding potential is greatly enhanced by the velocity of the round,\textsuperscript{52} based on the formula kinetic energy $= \text{mass} \times \text{velocity}^2/G$. Injuries result from the transference of energy from the projectile to organs and bony structures. With high-velocity rounds (velocities $>2000$ feet/second), a temporary cavity is formed along the wound tract and may be 11 or 12 times the diameter of the bullet and can result in tissue damage away from the physical tract taken by the projectile.\textsuperscript{39} Due to the amount of energy possessed and transferred to underlying tissue, exit wounds associated with centerfire rifles, in contrast to those associated with handguns, are generally larger than their corresponding entrance wounds (Fig. 62-12).\textsuperscript{35,36,37}

Entrance wounds associated with high-velocity, centerfire projectiles do not significantly differ from those of handguns. Entrance wounds will generally exhibit abrasion collars or microtears on the skin surface (Fig. 62-13). Wounds will also have associated soot deposition and tattooing, but because of a number of variables, such as muzzle length, amount of power in a given cartridge, muzzle configuration, and type of gunpowder, the range of fire in rifle wounds is not as clearly defined as in handgun wounds. The determination of an exact range of fire for rifles and shotguns is best established through controlled testing performed by a firearms examiner at a crime laboratory.

High-velocity lead core and jacketed bullets generally break up into hundreds of fragments, called a “lead snowstorm,” upon entering tissues, creating significant tissue damage (Fig. 62-14).\textsuperscript{35} If the tissue is deep, the bullet fragments may fail to exit and be embedded. Thus, it is possible to sustain an injury with a high-velocity round and not exhibit an exit wound. High-velocity rounds with steel cores will almost uniformly exit intact.

### Microscopic Examination of Wounds

The débrided epithelial margins of wounds should be submitted to the pathology department for a histologic examination to help determine wound entrance, exit, and range of fire.\textsuperscript{32-35}

### Evidence

A victim’s clothing may yield information about a bullet’s range of fire and help distinguish entrance from exit wounds.\textsuperscript{5,13,15,17,37-39,56} Clothing fibers will deform in the direction of the passing projectile.\textsuperscript{20} Gunpowder residues and soot will deposit on clothing as they do on skin. Residue may be invisible to the naked eye but can be visualized using standard forensic staining techniques for nitrates and vaporized lead. Some bullets, as they make initial contact with clothing, leave a lead or lubricant residue that is termed bullet wipe. Articles of clothing removed from a wounded patient need to be placed in separate paper bags to avoid cross-contamination of evidence.\textsuperscript{15}

A gunshot residue (GSR) test may determine whether a victim or suspect has fired a weapon.\textsuperscript{56,36,65} The GSR test checks for the presence of invisible residues from the primer: barium nitrate, antimony sulfide, and lead peroxide. The presence of residue can be checked by (1) swabbing the palms and the dorsum of the hands with a 5% nitric acid solution and then analyzing using atomic absorption spectrophotometry or (2) placing tape or an adhesive disk on the hands and then removing it for examination under a scanning electron microscope.

The specificity and sensitivity of the GSR test are unclear.\textsuperscript{26,31,34,65} Residue will deposit on the hands of the individual who fired the weapon in only 50% of cases.\textsuperscript{56} Residue
may spread throughout a crime scene, and secondary contact with the weapon or furniture on which residue was deposited will result in a false-positive test. The transferring of residue from police officers to suspects has also been reported. The sensitivity of the test decreases with time, and law enforcement agents may not have access to a patient during the “golden hour.” Factors that decrease sensitivity include washing the skin with alcohol or betadine, placing tape on the skin, rubbing the hands against clothing, and placing plastic bags over the patient’s hands, which precipitates moisture on the skin. If a GSR test is to be performed or if soot is noted on the patient’s hand, paper bags should be placed over the hands early in the treatment.

The bullet, the bullet jacket, and the cartridge case are invaluable when identifying or excluding a weapon. When a weapon is discharged, it imprints multiple unique microscopic marks on the side of a bullet and on the bottom or side of the cartridge case. The bullet’s markings result...
An exit wound from a high-velocity rifle round. Exit wounds from high-velocity rounds are generally larger than their corresponding entrance wounds. The large size is due to energy transfer from the projectile to underlying tissue with the expelling of tissue, principally bone.

An entrance wound from a high-velocity rifle round. Entrance wounds of high-velocity projectiles will also display an abrasion collar.

A "lead snowstorm" from a high-velocity rifle round. High-velocity projectiles have a tendency to fragment into hundreds of tiny particles upon contact with bone. This fragmentation contributes to the massive tissue damage associated with these projectiles.

Hemostats should be covered with gauze when removing bullets. Metal-to-metal contact destroys the microscopic marks, which are used to identify the weapon from which the bullet was discharged. From its contact with the tool marks or "rifling" in the gun's barrel. The marks on the cartridge case are from contact with the firing pin, the breechlock, the magazine of semiautomatic weapons, and extractor and ejector mechanisms. These microscopic fingerprints and markings can be obliterated by removing a bullet with hemostats or pickups. Bullets should be handled with gloves and surgical instruments covered with gauze (Fig. 62-15) to ensure the preservation of these microscopic "fingerprint" marks. It is not necessary to place initials or other markings on the bullet if adequate notes are made in the patient's medical record regarding the chain of custody.

Radiographs also help locate retained projectiles and may be of evidentiary value when determining the number of projectiles and the direction of fire.

FORENSIC ASPECTS OF PHYSICAL ASSAULT

Identifying Assault Victims

Studies estimate that 22 to 33% of patients in an urban emergency department are victims of domestic violence, yet very few are recognized as such. In a study of victims of domestic violence, 43% of patients with acute trauma presented to the emergency department 6 or more times before they were identified as victims of abuse; nearly half of these patients presented at least 12 times. Also, those admitted to the trauma service also go unrecognized.

Every weapon leaves a mark, design, or pattern stamped or imprinted on or just below the epithelium. The epithelial imprints of these weapons, called pattern injuries, are consistently reproducible. These injuries are classified into three major categories according to their source: blunt force, sharp force, and thermal.
Figure 62-17. Pattern contusion with parallel lines and central clearing from contact with a baseball bat.

Handcuff and shackle marks are generally more prominent on the lateral aspects of the extremity.

The history should be recorded and injuries documented with diagrams and photographs, when possible. The incident is best reviewed by an internal affairs unit of the investigating law enforcement agency and not by the emergency physician. Conclusions regarding the alleged perpetrator and mechanism should generally be avoided.
have been identified from bite marks up to 6 months after injury. The emergency physician may be asked to render an opinion regarding the age of a contusion. The development of a contusion is based on a number of variables: the amount of blunt force applied to the skin, the vascularity of the tissue, the fragility of the blood vessels, the density of the tissue, and the amount of blood that escapes into the surrounding tissue. As a result, no reproducible standard for the dating of a contusion is possible based on its color. New techniques based on reflectance spectrophotometry are currently being tested.

A tissue biopsy examining the hemosiderin breakdown may be the only scientifically accepted method to determine the approximate age of a contusion. Pattern Abrasions and Lacerations. A **pattern abrasion** is a rubbing or scraping away of the superficial layers of the epidermis (see Fig. 62-18), which is not important for treatment but may be invaluable from a forensic and injury reconstruction perspective.

A laceration is defined as a tear produced by blunt trauma and should not be confused with an incised wound produced when a sharp-edged implement (knife or scalpel) is drawn across the skin. A laceration has characteristically abraded or crushed skin edges and unique “tissue bridges” (Fig. 62-21).

**Sharp Force Pattern Injuries**

An **incised wound** is longer than it is deep, and the **stab wound** is defined as a puncture wound that is deeper than it is wide. The wound margins of sharp force injuries are clean and lack the abraded edges and tissue bridges of injuries resulting from blunt forces.

Forensic information can be gathered during the examination of a stab wound. Some of the characteristics of a knife blade, single edged or double edged, can be determined from visual inspection (Fig. 62-22A and B). Additional blade characteristics, such as serrated versus sharp, can be seen if the blade was drawn across the skin during its insertion or withdrawal (see Fig. 62-22C). Serrated blades do not always leave these characteristic marks.

**Thermal Pattern Injuries**

A thermal pattern injury is a common form of abuse or battery. The history should include the position of the patient relative
to the thermal source. This information will help determine whether the injury was intentional or accidental. Immersion or dipping burns are characterized by a sharp or clear line of demarcation between burned and unburned tissue. In contrast, splash burns are characterized by an irregular or undulating line or by isolated areas of thermal injury, usually round or oval in shape, caused by droplets of hot liquid.

The severity of thermal or scald injury depends on the contact length of time and the temperature. Water causes full-thickness damage in 1 second at 158°F (70°C) and in 600 seconds at 120°F (48.9°C) (Fig. 62-23). Law enforcement routinely measures the household's or institution's water temperature in any investigation involving a scald injury.

### FORENSIC ASPECTS OF MOTOR VEHICLE TRAUMA

Law enforcement officials investigating an incident involving serious or fatal injuries from a motor vehicle or pedestrian collision may benefit from information regarding injury patterns and the collection of trace evidence from the victim. This information can help determine whether an occupant was a driver or passenger. It may help to identify a suspect vehicle involved in a hit-and-run pedestrian collision or a pedestrian's position (standing or lying) when struck in the roadway.

Determination of a vehicle occupant's role may be simple, if the driver is pinned behind the steering wheel, or complex, if the vehicle's occupants are ejected. Many impaired drivers claim to be passengers. Short-lived evidence or pattern injuries that might be destroyed or altered in the delivery of patient care should optimally be preserved.

An opinion on an occupant's position should be avoided because the position is difficult to determine based solely on the statements and physical findings in the emergency department. Such an opinion is better based on an examination of the scene, the vehicle, other occupants, and information regarding trace evidence only after forensic examinations, including postmortem examinations, have been performed on all of the vehicle's occupants and all forensic evidence has been evaluated.
**Evidence Collection—Driver versus Passenger**

**Victim**
- **Examine for Pattern Injuries**
  - Steering wheel contusion
  - Radio knob contusion
  - Window crank contusion
  - Striated incised facial wounds
  - “Dicing” wounds
- **Examine Clothing for Transferred Material**
  - Glass (front and side windows)
  - Fibers
  - Pedal imprint on shoe
  - Dashboard components
- **Collect Biologic Standards**
  - Hair
  - Blood
- **Collect Clothing Standards**
  - Damage

**Vehicle**
- **Examine for Pattern Damage**
  - Steering wheel
  - Radio/knobs/dashboard
  - Window crank/side door
  - Windshield (laminated glass)
  - Side/rear window (tempered glass)
- **Collect Standards**
  - Glass
  - Carpets and seats
  - Gas and brake pedals
  - Broken dashboard components
- **Examine for Transferred Material of Pedestrian**
  - Hair on windshield/components
  - Blood on windshield/components
- **Examine for Transferred Material on Car Occupants**
  - Fabric fibers
  - Imprinted fabric pattern

**Pattern Injuries**

Matching pattern injuries with components within a vehicle often reveals an occupant’s position during a portion of the vehicle’s collision sequence. Common pattern contusions, abrasions, and lacerations are seen from steering wheels, air bags, air bag module covers, window cranks, radio knobs, door latches, dashboard components, and front and side window glass. An occupant’s movement and subsequent contact with a vehicle’s components are dictated by the forces applied to the vehicle through its interaction with the environment. Vehicle occupants, restrained or unrestrained, will initially move toward the primary area of impact. This movement within the vehicle, called occupant kinematics, is described as a motion parallel to and opposite from the direction of the force developed by the impacting object and can predict the direction a particular occupant will move and therefore what component will be struck.

A deploying air bag may induce a pattern abrasion to the face, cornea, forearms, or other exposed tissue. Pattern lacerations, specific fracture patterns, and amputations are seen when the deploying air bag module cover impacts the hand or forearm (Fig. 62-24). The correlation of these injuries to the driver or passenger air bag system is helpful in assessing an occupant’s role.

Laminated (windshields) and tempered (side and rear windows) glass produce pattern injuries. The windshield is composed of two layers of glass laminated together with a thin layer of clear plastic sandwiched between. Laminated glass breaks into shards on impact and causes linear incised wounds. Tempered or “safety” glass is a single layer of glass that breaks into small cubes when fractured, imparting a “dicing” pattern to the skin.

**Trace Evidence**

Clothing, shoes, and biologic standards (hair and blood) may determine an occupant’s role. The soles of leather shoes may reveal the imprint of the gas or brake pedal (Fig. 62-25). Preservation of clothing permits comparison of clothing fibers with those fibers transferred to vehicle components during the collision. Imprints of fabric may also be transferred to components within the vehicle, including the steering wheel. Contact with the windshield often transfers hair and tissue to the glass. Glass collected from within a patient’s wound can...
be matched with a particular window within the vehicle. Airbags are also a tremendous source of trace evidence including skin, blood, makeup, and hair (Fig. 62-26).

**Evaluation of Pedestrian Collisions**

**Pattern Injuries**

Approximately 66,000 people are killed or seriously injured annually in pedestrian collisions; 87% are struck by a vehicle’s front bumper/grill area. When struck by the front of a vehicle, a standing adult will sustain “bumper injuries,” which include open and closed fractures of the tibia and fibula, soft tissue damage, and pattern injuries from vehicle components and hardware.

The height of bumper injuries, measured from the heel and including the height of the patient’s shoe, can be correlated with the height of the vehicle’s bumper to determine whether the vehicle was braking at the moment of impact. Application of the brake results in the dipping of a vehicle’s front end. The presence or absence of braking may help determine the driver’s intent. The presence of bumper injuries at one height on one leg and at another height on the other may indicate that the pedestrian was walking or running at the moment of impact, with one leg elevated. Examination of the soles may show lateral striations when a patient has been dragged.

A victim who is struck from behind may have pattern contusions on the calf or thigh (Fig. 62-27), whereas pattern contusions from a grill on the anterior aspect of the thigh indicate the pedestrian was standing and facing the vehicle. Pedestrians struck by a glancing portion of a vehicle may also display a pattern injury (Fig. 62-28). Victims who are run over may display a tire tread pattern. Tire marks and the absence of bumper injuries may indicate that the patient was supine or prone in the roadway (Box 62-3).
Figure 62-28. A, Three horizontally oriented wounds were noted on the back of a pedestrian struck by a semi-tractor trailer on a highway while changing a flat tire. B, The pattern injury was matched to the lug nuts of the front right wheel.

**BOX 62-3 EVIDENCE COLLECTION—PEDESTRIAN COLLISIONS**

**Victim**
- Examine for Pattern Injuries
  - Height of bumper injuries
  - Contusion
  - Fracture
  - Head/neck injuries
  - Crush injuries
- Examine Clothing for Transferred Material*†
  - Paint
  - Glass (windshield, headlight)
  - Oil or grease
- Collect Biologic Standards†
  - Hair
  - Blood or tissue
- Collect Clothing Standards†
  - Damage or tears

**Vehicle**
- Examine for Pattern Damage
  - Bumper height and damage
  - Specific components
  - Windshield damage
  - Wheels and undercarriage
- Collect Standards
  - Paint
  - Glass
  - Oil or grease
- Examine for Transferred Material of Pedestrian
  - Hair
  - Blood or tissue
- Examine for Transferred Material on Vehicle
  - Fabric fibers
  - Imprinted fabric pattern

*Each article of clothing should be collected in a separate paper bag. This avoids cross-contamination, and wet material will dry. Do not collect evidence in plastic bags because moisture will condense within the bag and may degrade biologic material.

†Each article should be marked with the patient’s name, item collected, date and time collected, location of collection, name of the collector, and name of law enforcement official to whom the evidence was given. This information will preserve the “chain of custody.”

**KEY CONCEPTS**

- Knowledge of wound mechanics and production, as well as wound appearance, can provide practicing emergency physicians with important clues to the forensic interpretations of injuries.
- Wounds and injuries should be diagrammed and photographed.
- The medical record should accurately document objective findings but should not speculate on the cause or mechanism.
- Any evidence collected in the course of treatment must be documented in the medical record, including to whom the evidence was given, in order for the chain of custody to be preserved.

PERSPECTIVE

Background

Child maltreatment is an all-encompassing term that includes all forms of child abuse: physical abuse, sexual abuse, emotional abuse, child neglect (physical, emotional, educational), and factitious disease by proxy (also known as Munchausen syndrome by proxy). Although the recognition of these conditions by the medical community has occurred at different times, the pivotal report describing child physical abuse occurred in 1962 with the publication of the article “The Battered Child Syndrome” by Kempe and colleagues. The article noted the presence of a complex of physical findings, including fractures, cutaneous bruises, and internal injuries. Since that time, multiple articles and books have described the spectrum of the disorders. During the 1980s, much of the literature focused on child sexual abuse, including the refinement of understanding of normal anogenital anatomy of prepubescent children. Child sexual abuse is defined as the involvement of children and adolescents in sexual activity to which they cannot give consent based on their developmental level, involving an age disparity between the victim and the perpetrator, and for the sexual gratification of the older individual. Child sexual abuse may involve physical contact between the child and the adult or the involvement of the child in other activities, such as photography or the production of pornographic material.

The role of the physician in caring for an abused child is multifold. Most importantly, the physician should recognize which presenting complaints are attributable to child abuse and initiate medical management of diagnosed medical conditions, some of which may be life-threatening. Differentiating between inflicted injuries, noninflicted injuries, and other medical conditions is paramount to the correct diagnosis and the proper management of the case. In addition, the clinician has the primary responsibility for reporting the suspicion of child abuse to the appropriate authorities, which usually include child protective services and law enforcement.

Epidemiology

There are over 1 million suspected child abuse and neglect cases noted annually in the United States. Table 63-1 summarizes the data by category of abuse or neglect as noted by the 2005 Child Maltreatment report from the U.S. Department of Health and Human Services. Although child abuse occurs across the spectrum of race, ethnicity, and socioeconomic class, certain factors are associated with an increased prevalence of abuse, including poverty, social isolation, parental alcohol and substance abuse, parental mental illness, and domestic violence.

PRINCIPLES OF DISEASE

Child Physical Abuse

Child physical abuse refers to the infliction of injury on any part of a child’s body. Injuries may be manifest in myriad forms to include cutaneous bruises, burns, skeletal fractures, internal hemorrhage, organ perforation, and brain injury.

Bruises may appear as petechiae or ecchymoses. They occur at the point of impact between the striking object, such as the hand, and the child’s body. Often they mirror the form of the inflicting object and may appear as a hand print, belt outline, or other object (Fig. 63-1). These bruises are referred to as patterned injuries. When the blow occurs at high velocity, the bruising may resemble the outline of the object as the soft tissue in the center of the impacted field moves laterally (negative image). When the thrust of the strike is slower, the central portion of the skin also may be discolored (positive image). The extent of an injury is influenced by many factors, including the force of blow and the area struck. Frequently the struck area initially may be only erythematous, swollen, or tender, and 24 hours may lapse before bleeding into the skin and subsequent discoloration are noted. The degree of discoloration and the rapidity of resolution of the discoloration are influenced by the location of the injury; large muscle masses, such as the buttocks, can hold larger volumes of blood, and resolution takes longer. In general, extravasated blood goes through a predictable color change pattern as it resolves, progressing from purple to green to yellow and eventually to brown. However, the color of a bruise should not be used as a tool to estimate the age of a bruise. Accidentally incurred bruises tend to occur over bony prominences, such as the shin and forehead. In addition, nonambulatory children (<1 year old) do not readily sustain accidental cutaneous injuries (“those who don’t cruise, don’t bruise”). Bites also produce a patterned injury. The distance between the maxillary canine teeth helps establish whether the perpetrator was a child (<2.5 cm), which is often alleged, or an adult (>3 cm).

Burns may be inflicted through contact with a dry hot object or through immersion in hot water. Commonly inflicted burns...

are secondary to contact with a cigarette, as opposed to inadvertent contact with a lit cigarette, which tends to create less severe or linear burns. Inflicted cigarette burns are usually circular, measuring 8 to 10 mm (Fig. 63-2). Initially they have a blistered appearance but then become ulcerated and crust over. Burn injuries also may assume a patterned appearance resembling the configuration of the hot object, such as a heating grid or an iron. Immersion burns occur when a child or infant is placed in hot water. Such burns often involve the anogenital area and may represent punishment for toilet training accidents, or they involve the hands or feet (glove-stocking distribution) that have been dunked in hot water. Immersion burns are usually second-degree burns (Fig. 63-3). The extent of the burn is influenced by the temperature of the water, the body site exposed (the skin is thinner in certain areas, such as the anogenital region), the age of the individual (younger children and elderly adults have thinner skin), and the duration of the contact between the hot object and the skin (Table 63-2).12 Patients with burns of the hand and feet or anogenital region require specialty care and for many emergency medical service systems, once stabilized in the emergency department will be transported to a burn center. Escharotomy may be required in selected cases when the burns are circumferential and severe.

Accidental burns can occur in children and usually involve scald injuries, which happen when children spill hot liquids such as coffee down their shirts. Spill burns have a characteristic drip appearance, with more extensive and severe injury proximal to the point of contact and less extensive and milder injury more distally. Disposable diapers are very absorbent of heat as well as of liquids. Scald burns in the anogenital area that are attributed to hot beverages falling into a child’s diaper should be scrutinized carefully, and if there is any concern of abuse a report should be made.13
Skeletal injuries may involve any of the bones in the body. Although approximately 42% of boys and 27% of girls have sustained a fracture before the age of 16 years, certain fractures are highly suspicious of an inflicted injury (Table 63-3). In particular, metaphyseal fractures, rib fractures, and certain types of skull fractures should raise concern about inflicted trauma (Fig. 63-4). Metaphyseal fractures (i.e., classic metaphyseal lesions) occur because of yanking or pulling on an extremity. On radiographs, they may appear as chips or what is referred to as a *bucket-handle injury* of the long bone (Fig. 63-5). They usually are noted in children younger than 2 years. Rib fractures, particularly posterior rib fractures in a small infant, are virtually pathognomonic for inflicted injury (Fig. 63-6). The rib cage, because of its archlike structure, must be subjected to a good deal of force to cause disruption. Rib fractures are extremely uncommon as a consequence of cardiopulmonary resuscitation. The presence of multiple skull fractures and skull fractures in the occipital region are unusual in cases of accidental trauma and should raise concern for inflicted trauma. Fractures that are diastatic (>3 mm in width), grow in size, or involve more than one cranial bone are less specific as markers for nonaccidental trauma; however, they are usually associated with mechanisms of injury that involve greater traumatic forces.

Head injuries, including those associated with the classically described “shaken baby syndrome,” account for most child abuse–related fatalities. The syndrome includes evidence of head trauma in association with retinal hemorrhages and skeletal injuries and occurs generally in infants younger than 1 year but may be seen in children up to 3 years old. Often, there is no evidence of an impact injury to the head, such as a scalp hematoma or skull fracture. The impact may be against a soft or compressible surface, such as the mattress of the crib. Such an impact results in a rapid deceleration of the head, and the brain experiences a coup-contrecoup injury by moving back and forth within the confines of the skull. Shaking of an infant or young child subjects the brain to rotational acceleration, which is capable of generating greater force and speed than linear acceleration, the type of acceleration that occurs with a fall. It has been postulated that severe repeated shaking of an infant or young child can lead to disruption of

</table>
the neuronal cells, with or without the presence of either subarachnoid or subdural hemorrhage. Hemorrhage is a marker for the event but may be of limited clinical significance, and death, when it occurs, may not be related to bleeding, brain compression, or brain displacement. Injury to the brain cells is referred to as traumatic axonal injury. This injury results in disruption of the cell membrane and subsequent cerebral edema. Cerebral edema impedes the cerebral circulation, which results in further hypoxic damage to the brain. At autopsy, special staining techniques allow for the recognition of axonal injury, which may be diffuse (diffuse axonal injury).

Retinal hemorrhages are another common associated finding and are reported to be present in about 75% of cases of shaken baby syndrome. The pathophysiology of retinal hemorrhages is uncertain. It is unclear whether bleeding is a result of increased intracranial pressure that is transmitted to the eye or occurs directly within the eye itself, perhaps through increased pressure along the retinal vein with subsequent disruption of the vessel. Additional theories propose a potential role of hypoxia and of direct vitreal traction on the retina with rotational head movement, resulting in torn retinal vessels. Retinal hemorrhages may involve the area in front of the retina (pre-retinal hemorrhages), the vitreous, and the subretina in addition to the retina. Hemorrhages may be described as “dot and blot” hemorrhages or flame or splinter hemorrhages. Clinically, the hemorrhages may be localized or extend to the ora serrata (the retinal edge). Retinal hemorrhages have been shown to not result from typical resuscitation efforts but could result from a severe blunt force mechanism such as a motor vehicle collision or a fall from a great height.

Abdominal trauma accounts for about 10% of injuries in abused children and carries a sixfold higher mortality rate than abdominal trauma due to accidental means. Trauma is often blunt and includes blows and kicks to the abdomen. Frequently, there is no external evidence of the injury because the force has been transmitted to the intra-abdominal structures. Injuries can include lacerations to the liver (more commonly) or the spleen. In addition, children may develop duodenal hematomas, an injury that leads to symptoms of upper intestinal obstruction. Perforations of the intestine or other hollow viscera can follow a blow to the abdomen with subsequent progression to secondary peritonitis. Pancreatitis is also a sequela of inflicted abdominal trauma, and the latter is said to be the most common mechanism of non–medication-associated pancreatitis in children.

Child Sexual Abuse

Physical findings present when a child or adolescent has been sexually abused depend on the nature of the abuse, the time since the abuse, and whether the abuse was repetitive or isolated. Acute injuries include disruptions (tears) of the hymen, petechiae, hematomas, or rarely vaginal tears. The prepubescent hymen is significantly more fragile and more easily traumatized than the postpubertal hymen, which thickens and becomes redundant under the influence of estrogen. Physical changes in the anogenital area also may be noted when there has been prior or recurrent sexual abuse. Changes include loss of hymenal tissue and the appearance of U-shaped disruptions in the hymenal contour. Anal findings include the presence of scars and changes in anal tone and the anal contour. Evidence of recent trauma also may be visible in the anal area. Acutely, there may be lacerations that appear as perianal fissures, which are characteristically wider distal to the anus. There may be post-traumatic dilatation, or alternatively anal spasm may occur in response to submucosal injury. In abused boys, the penis rarely has a noticeable injury. More recent studies have evaluated genital healing that occurs after traumatic injury.

## CLINICAL FEATURES

### Signs and Symptoms

#### Child Physical Abuse

Children who have been physically abused may have complaints related to the abuse, or injuries may be noted during the course of an evaluation for an unrelated medical condition. Infants with head injuries may present with nonspecific symptoms that go unrecognized as being related to inflicted head trauma. These symptoms may include apnea, altered mental status, an apparent life-threatening event, vomiting, or a seizure. Clinicians should remain alert that these symptoms may be related to intracranial bleeding or elevated intracranial pressure. A careful physical examination should include an attempt to visualize the eye grounds to determine if there is any evidence of retinal hemorrhages. Bruises on a young infant’s face are suspicious for head injury.

Refusal to use an extremity or to bear weight may be an indication of a fracture. Similarly, swelling of an extremity may be a sign of a skeletal injury.

Children with abdominal injuries may present with abdominal pain, vomiting, abdominal distention, or shock. In cases of inflicted trauma, the history may be unremarkable or may be inconsistent with the medical findings. It is common for a parent to state that he or she is uncertain how a child sustained the injury, or that the child was well at bedtime and awoke in the morning refusing to walk or with severe abdominal pain. Caregivers should be queried about how they think the injury was sustained. In cases of inflicted head trauma, the scenario often includes a young infant left in the care of a male friend or partner of the mother who has gone to work or to run errands. The male companion asserts that the infant was fine, sleeping in the crib when he went to take a shower or make some coffee, and when he returned to check on the infant, the infant was not breathing or was seizing. Often the mother is called before calling 911, or the infant is scooped up by the individual and carried to a hospital. The part of the history that is omitted is that the infant was crying, and the companion shook the infant and thrust the infant back into the crib. The infant sustained acute traumatic axonal injury and stopped crying. The infant is then left unattended, seemingly asleep. As bleeding and cerebral edema develop, other symptoms intervene. Sometimes a family member fallaciously relates a history of a fall, usually from a height (<25 inches from the ground) to a floor that is often carpeted. Or the family member may relate that a young sibling, for instance an 18-month-old, hit or jumped on the infant. Such events are not consistent with severe intracranial injuries.

Histories of falls also are related in children presenting with severe inflicted abdominal trauma. Although falls may lead to bruises of the abdominal wall and rarely damage to solid organs, they are unlikely to cause intestinal injury such as duodenal hematomas or intestinal perforations. In addition to obtaining a history of the current event, past medical, developmental, and social histories are important. In children presenting with acute injuries consistent with physical abuse, there is the possibility that the findings or their severity may be related to an underlying medical condition. A careful medical history may help exclude such conditions or bring these disorders into consideration. A history of epistaxis and bleeding gums in a child who presents with bruises suggests an underlying coagulopathy. A family history of fractures raises the possibility of a bone disorder, such as osteogenesis.
imperfecta. Documenting a developmental history is important when attempting to assess the likelihood that children’s injuries were related to their own activity. It is crucial to be suspicious of injuries in young infants who have limited motor skills. A caregiver may allege that a 3-week-old infant sustained a head injury when he or she fell after having been placed in the center of the bed, but a 3-week-old infant is developmentally unable to scoot or roll from the center to the edge of the bed. The developmental history should document major milestones, such as age of rolling over, sitting unsupported, crawling, and walking.

A social history also is important. It may be helpful for a social worker to assist with a comprehensive social interview, but the clinician can obtain basic information, such as family financial resources (e.g., are the parents working?), where the family lives, what the family’s support system is (is there extended family around?), whether there has been domestic violence within the family unit, whether there is substance abuse, and whether the family has ever been reported to child protective services.

A comprehensive physical examination should be conducted. Growth parameters should be obtained and plotted to determine if there is evidence of growth impairment or failure to thrive. It is helpful to have a diagram or outline of the body to allow for precise documentation of the size and location of bruises. In addition to the routine examination, there should be a thorough inspection of the infant to detect areas of swelling or tenderness as might occur with fractures. The abdomen should be palpated carefully for tenderness or masses. A careful ophthalmologic examination should be carried out. It is frequently difficult to visualize the fundi of young infants without the benefit of pupil dilation and an indirect ophthalmoscope. Specialized retinal cameras allow for documentation of the findings; often ophthalmologic consultation is requested to assess the fundi.

Child Sexual Abuse

Children who have been sexually abused may present with complaints related to an abusive event (e.g., “my Uncle Joey touched me”), anogenital injuries, or other related anogenital physical findings, such as a vaginal discharge. Some children present with stress-related symptoms, such as recurrent headaches or abdominal pain. Concerns about sexual abuse may be raised by divorcing parents when child custody is in dispute. Other patients, particularly older children and adolescents, may be brought to the emergency department by investigative agencies for a physical examination because of a disclosure about recent or prior abuse, even in the absence of any physical or medical complaints.

The medical evaluation should include a history of the events surrounding the alleged molestation. If the child is verbal and willing to disclose to the clinician, this information should be obtained and recorded in the medical record using the patient’s own words as much as possible. The report with the disclosure is admissible as evidence. In other cases, the history may be related by other individuals, such as parents, social workers, or law enforcement officers, who are accompanying the patient. The history should include who did what, when, where, and how often. To facilitate communication and understand what the child is discussing, inquiring about the terms the child uses for different parts of the body can be helpful.

Past medical history also should be noted, including previous anogenital injuries, surgeries, or symptoms such as the presence of vaginal discharges or recurrent urinary tract infections. Stool patterns should be noted and, if constipation is reported, whether any anal medications (suppositories or enemas) are used. In postpubertal girls, a menstrual history, including age of menarche and type of sanitary protection, as well as a sexual history, should be recorded.

The physical examination should include a full head-to-toe assessment to determine if there are acute nongenital injuries (e.g., grip marks or oral injuries) or dermatologic conditions, such as lichen planus, which may explain changes in the anogenital area. The anogenital examination should note the level of pubertal development, recording if the child is prepubertal or at a more advanced stage of sexual maturity. Prepubertal children should be examined using a multimethod approach. Initially, children should be evaluated in the supine position. The labia majora and surrounding tissues should be assessed for evidence of injuries or other abnormalities. Separation or traction should be applied to the labia to visualize the structures covered by the labia majora. In prepupal children, the labia majora are large and full and cover the underlying area. The labia minora are small and delicate and do not fully encircle the vaginal orifice. The clitoris and urethra should be examined. The hymen should be inspected visually for evidence of disruptions and irregularities. The hymen should be precisely described—the phrase “hymen intact” is not sufficiently descriptive for the purposes of a forensic medical assessment. An appropriate description would be “hymen pink, annular, with smooth thin edge and no disruptions.” The hymenal diameter is difficult to measure reliably and an enlarged hymenal orifice without other changes in the hymen is not thought to have forensic significance. Prepubertal girls also should be examined in the prone knee-chest position. The hymen often relaxes more fully in this position, allowing for a more thorough assessment. Speculum examinations are neither indicated nor appropriate for a prepubertal child. If intravaginal trauma is suspected on the basis of vaginal hemorrhage, examination of the child in the operating room under anesthesia is mandatory. Postpubertal adolescents should be examined using a traditional pelvic examination table with stirrups. In cases of acute sexual assault, a full evidentiary assessment, including speculum examination for the purpose of evaluation and collection of forensic material, is indicated.

DIAGNOSTIC STRATEGIES

Child Physical Abuse

Diagnostic studies should be done to determine the extent of the injuries, detect occult injuries, and exclude medical conditions that may account for the findings. If there is evidence of hemorrhage, such as cutaneous bruises or intramuscular hematomas, coagulation studies are indicated. As a baseline, these studies would include a platelet count, prothrombin time, and partial thromboplastin time. It would be appropriate also to obtain a complete blood count to rule out a blood dyscrasia, such as leukemia in a child who presents with multiple ecchymoses. Occasionally, rarer coagulation deficiencies may present with bruising; the detection of such disorders requires more specific diagnostic studies. In a child with suspected burn injuries, skin cultures are appropriate to rule out infections with Staphylococcus aureus, such as occur with bullous impetigo.

In general, children younger than ages 2 to 3 years with suspected inflicted injuries should be evaluated with a skeletal series, sometimes referred to as a trauma X or trauma series. A trauma series includes radiography of the skull, long bones, ribs, and vertebrae. The presence of multiple fractures, particularly ones in different stages of healing, is the hallmark of the battered child syndrome. Acutely, some fractures, such as
rib injuries, may not be readily visible. Repeat radiography in 1 to 2 weeks shows evidence of callus formation and makes the fracture more readily appreciated. Alternatively, a radiograph bone scan can detect subtle injuries and should be obtained if there is a skeletal injury but a negative skeletal survey.

Urinalysis, liver function studies, and serum amylase and lipase levels should be considered in children with symptoms of abdominal injury, such as vomiting, abdominal pain, or guarding. Plain x-rays are rarely helpful but should be considered if clinical findings suggest perforation or obstruction. Computed tomography scans of the abdomen are a more precise way of delineating any abdominal injury. Computed tomography scan of the head is indicated when symptoms are consistent with head trauma or in an infant with facial bruising. Computed tomography scans may reveal extra-axial hemorrhage or findings consistent with cerebral edema. If the child is sufficiently stable, magnetic resonance imaging is helpful in determining the age of the hemorrhages and in assessing whether there has been prior intracranial hemorrhage.

In recent years, certain metabolic disorders have been described that also may be associated with intracranial hemorrhage. In particular, glutaric aciduria type I may be mistaken for inflicted head trauma. Urinalysis for organic and amino acids would detect this condition.

A careful ophthalmologic examination is crucial. The examination is best done by a pediatric ophthalmologist. Photographic recording of the retinal findings is an important part of the diagnostic workup. Photographing cutaneous injuries is also important and frequently can be carried out by a police criminalist, whose equipment includes color bars for accurate documentation of the coloration of the bruising.

Child Sexual Abuse

Child sexual abuse assessments are sometimes best done with equipment that allows for magnification of the genital tissue. An otoscope or hand-held magnifier is usually available in an emergency department. Centers that evaluate sexually abused children often use colposcopes with photographic or video capability or both to allow for recording of the physical findings. Magnification allows for the detection of microtrauma or small changes in the hymen that may not be readily apparent to the naked eye. Toluidine blue is a stain that is used to increase the ease with which minor injuries are detected. The dye is selectively taken up by exposed endothelial cells. The collection of forensic specimens for the detection of sperm or for the retrieval of DNA of the alleged perpetrator is indicated in cases of acute sexual assault.

Evaluating a child or adolescent for the presence of a sexually transmitted infection depends on many factors, including disease prevalence in the community, patient symptoms, and the nature of the abuse. In cases of acute assault, the recommendation is often to treat the patient prophylactically against sexually transmitted infections such as gonorrhea and chlamydia. The decision to offer prophylaxis against human immunodeficiency virus is often based on disease prevalence and other risk factors (Table 63-4).

Part of the assessment of a sexually abused child may include a detailed interview. Forensic interviews are carried out by an individual with expertise in interviewing children, such as a social worker or clinical psychologist. Although the preliminary interview may be carried out in an emergency department, a more in-depth interview often takes place in a diagnostic center where it may be videotaped or observed (through a one-way mirror) by other individuals, such as law enforcement officers or criminal prosecutors, to minimize the number of times a child or adolescent needs to be questioned about the alleged abusive events.

### DIFFERENTIAL CONSIDERATIONS

#### Child Physical Abuse

The major differential diagnosis when considering child abuse is unintentional injury. Differentiating between inflicted and noninflicted injuries requires the consideration of multiple factors, including the developmental stage of the child, the extent of the injuries, whether the injuries appear to have occurred over a period of time, whether there were witnesses to the alleged event, whether medical care was sought in a timely manner, and whether the injuries could have been sustained in the stated manner. It is important for the evaluating clinician to have an understanding of normal child development, particularly the acquisition of motor skills. Children who are ambulatory, particularly toddlers and young school-age children, are prone to bruises over bony prominences, such as the shins and forehead. Noninflicted bruises are usually unilateral, occurring on the side where a fall or collision with a solid object has occurred. Bruises on the buttocks and flank must be explained by the mechanism of injury and are unusual in noninflicted trauma.

**PART II**

**Trauma / Section Five - Violence and Abuse**

**Violence and Abuse**

Fractures occur with increased frequency and with lower amounts of force in certain conditions. Premature infants may experience osteopenia of prematurity (sometimes referred to as rickets of prematurity), the radiographic appearance of which can be mistaken for a metaphyseal fracture. In addition, osteopenic bones may fracture more easily. More advanced cases of osteopenia can be noted on a plain film of the bones. Osteogenesis imperfecta is a condition in which the bone is more brittle and easily disrupted. There are four types of osteogenesis imperfecta, each with a different gene frequency. The overall incidence of osteogenesis imperfecta is 1 in 20,000. Generally, osteogenesis imperfecta is associated with other clinical findings, such as blue sclerae and brown discoloration of the teeth (dentogenesis imperfecta). Rarely, bone fragility may be present in isolation. Scurvy, congenital syphilis, and congenital rubella are associated with bony changes that may be misinterpreted as evidence of prior bony injury.

Cerebral edema may occur with infection, such as encephalitis and meningitis, or after a hypoxic event. The history and the presence of associated medical findings help with the differentiation of these conditions.

**Child Sexual Abuse**

Numerous medical conditions may be misdiagnosed as child sexual abuse. Accidental trauma, most commonly straddle injuries, may occur after a fall onto the perineum. Such falls occur with climbing on monkey bars, riding on boys’ bicycles, or exiting from a swimming pool. Straddle injuries usually involve the labia minora, labia majora, or perineal area. The hymen remains uninjured. Lichen sclerosis et atrophicus is a dermatologic condition of unclear etiology affecting prepubertal girls and boys and postmenopausal women. The hymen is unaffected, but the adjacent skin becomes atrophic and may sustain blood blisters or petechiae. Characteristically the skin in the perianal and perihymenal areas becomes hypopigmented and surrounds these orifices with a pale figure-of-eight configuration.

Urethral prolapse characteristically affects African American girls between the ages of 5 and 8 years. The mucosal lining of the urethra slides forward and protrudes from the urethral orifice, appearing as an erythematous, edematous mass. Symptoms include pain and bleeding. Management may involve sitz baths, antibiotic ointment, or referral to a urologist for ligation. Vaginal discharge may occur secondary to conditions other than sexually transmitted infections. *Shigella*, group A beta-hemolytic streptococci, *Candida*, pinworm infestation, and vaginal foreign bodies can cause a vaginal discharge.

Penile swelling may occur with priapism (often secondary to sickle cell disease), paraphimosis, or an infestation with chiggers. Fissures and tags in the perianal area may result from trauma, but also may be associated with constipation and inflammatory bowel disease. Group A beta-hemolytic streptococci can cause painful inflammation with erythema in the perianal area. Affected children may be febrile and experience pain with defecation. Hemorrhoids are rare in children and are associated with conditions that lead to an elevation of intra-abdominal venous pressure as occurs with cirrhosis of the liver.

**Management**

The focus of management is to attend to serious or life-threatening injuries, such as significant head or abdominal trauma, and stabilize the patient. Physical problems requiring medical intervention, such as fractures, lacerations, burns, or sexually transmitted infections, should be managed...

*Figure 63-7. Mongolian spots in an infant. (Courtesy of the EMSC Slide Set, National EMSC Resource Alliance.)*

Mongolian spots are bluish discolorations that are seen normally over the buttocks and lower spine in children with darker complexions (Fig. 63-7). Mongolian spots can appear on other parts of the body, such as the face and upper arm. They are usually present from birth but may not appear until the infant is several weeks old. When seen in a typical location, they are readily recognized as Mongolian spots. When located elsewhere on the body, they may be mistaken for bruises. Bruises resolve over time, Mongolian spots remain unchanged (do not go through purple-green-yellow-brown transformation) because they are undistributed melanocytes.

Phytodermatitis also may be mistaken for bruises. This is a condition that develops on sun-exposed areas of the body that have been in contact with certain fruits or juices, such as lime or lemon juice. The lesion appears as a brown discoloration, which may take the shape of the dripped juice or the object with which the juice came in contact. For instance, if a mother is making lemonade, has the lemon juice on her hand, and holds her child, a brown discoloration in the form of a handprint may appear if the child is in the sun. These lesions fade over time, and with a careful history and physician familiarity with the condition, the correct diagnosis can be made.

Burns also may occur unintentionally. Unintentional burns are usually secondary to spills and may take the form of drip marks down a child’s chest. Bullous impetigo can be mistaken for second-degree burns because of its blister-like appearance. Culturing the lesion reveals the presence of *S. aureus* in the case of bullous impetigo. Certain dermatologic conditions, such as epidermodysplasia bullosa, also may cause bullous lesions that may resemble second-degree burns. The history and generalized appearance of these lesions help establish the correct diagnosis.

Fractures may occur unintentionally. In young infants, fractures may be a result of birth-related injuries. The most common fractures sustained during birth are clavicular and humeral fractures. These fractures may not be appreciated immediately after birth but become apparent when callus formation is noted. Ambulatory children may sustain fractures related to falls. A toddler’s fracture, also referred to as a CAST fracture (childhood accidental spiral tibial fracture), occurs when there is a twisting injury to the tibia as the child falls on it. In general, the fracture is a nondisplaced distal fracture of the tibia that is detected when a child presents with a limp. Sometimes the fracture may not be apparent on the initial radiograph, but delayed radiographs (1–2 weeks after injury) may show callous formation or a bone scan may show the presence of increased bony uptake.
appropriately. Key to the ultimate management of the abused child is the precise recording of the pertinent history, particularly any disclosure made by the child, and the physical findings. Most states require the completion of a specific child abuse reporting form as a means of notifying the authorities about the suspected case of child abuse. In addition, many jurisdictions require immediate telephonic notification to initiate an investigation of the circumstances surrounding the abuse.

Disposition

Admission to the hospital may be warranted because of the patient’s injuries, to complete the medical evaluation, and to protect the child while the evaluation is occurring. Many hospitals have suspected child abuse and neglect (SCAN) teams. These teams can offer expert consultation either in the emergency department or after the child has been admitted. SCAN teams usually have unique expertise in assessing the genital findings in prepubertal girls.

Issues may arise with the family regarding “allowing” the child to be admitted to the hospital once the concerns of the emergency physician are related to the family. A strong security presence is advised during both disclosure of the intent to file a report of possible child abuse and when the decision is made to admit the child to the hospital. If security is not available to provide support to the emergency physician, and there is concern for personal safety, the addition of other hospital personnel should be solicited.

The outcome for an abused child varies with the nature, extent, and duration of the abuse. Some children die as a result of their inflicted injuries. Others have irreversible brain damage and may spend the remainder of their lives confined to wheelchairs or be blind or otherwise disabled. For other children, intervention and therapy for themselves and their offending parents may help reverse the adverse psychological effects of the abuse. The emergency physician has a key role in the early detection of the problem. The entire medical team, along with social services, law enforcement, and the judicial system, is responsible for implementing a treatment plan that prevents recidivism.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
CHAPTER 64  Sexual Assault
Laura Slaughter

PERSPECTIVE

Background

Sexual violence is a significant problem in the United States. The Centers for Disease Control and Prevention have defined it as sexual activity where consent is not obtained or freely given. It pertains to a wide variety of sexual conduct and may entail, but does not require, penetration, completion, or, in certain cases, physical contact (e.g., voyeurism). Referred to in statute as sexual assault, it is explicated more precisely by state and local governments. Emergency physicians must be aware of their local laws because they are mandated reporters and may be involved in the evaluation, treatment, evidence collection, and documentation of sexual assault. 1

Major advances in the evaluation and management of sexual assault victims (SAVs) have occurred over the past 30 years. The formation of community-based multidisciplinary teams that first took hold in California is probably the most important. The development of a sexual assault response team (SART) with representatives from the District Attorney’s office, law enforcement, crime laboratory, medical personnel, including both physicians and nurses, social service agencies, and victim advocates came together as a group. These major players have sought to solve the logistical, medical, psychological, legal, and social problems incurred by SAVs. The commitment and mutual cooperation of the SART led to the development of standardized protocols for the care and treatment of SAVs. These protocols specify the procedures for interviewing and examining the SAV, collection, preservation, and storage of evidentiary materials, and include the evidence kit and forms for documentation. Many jurisdictions have adopted this standardized system, and in 2004 the first national protocol was released by the U.S. Department of Justice. 2 With a protocol in place, the necessity of having trained forensic examiners (FEs), irrespective of academic credentials, is evident. 3 Currently, this role subsumes the sexual assault nurse examiner (SANE); these ubiquitous, mostly hospital-based SANE programs have contributed substantially to our knowledge and understanding of SA and improved the care of these victims. 4, 5 Additionally, because of the use of special technologies, including colposcopy, digital photography/videography, and the alternative light source, the establishment of designated examination centers for sexual violence is increasingly popular. 6 Much information about the characteristics, physical examination findings, and correlates of injury in SAVs is now available. This information facilitates the management of the SAV, improves the experience of the victim, and, ultimately, will assist in the identification of the perpetrator.

Epidemiology

Sexual assault does not seem to be declining at the rate of other violent crimes; nearly every category of crime was significantly lower in 2001–2002 than in the preceding 2 years except for SA. 7, 8 Importantly, the cost of sexual violence to the health care system is high because it may include not only the initial visit for the crime but also subsequent visits for other health issues. 9

Women remain the predominant victims (94%). Historically, SA has been a largely unreported crime, with only about a third of SAVs coming forward. The major reasons given for not reporting include that the matter was personal, fear of reprisal, or fear of police bias. The closer the relationship between the victim and offender, the less likely the SAV has been to report the crime; the relationship between SAV and perpetrator is often absent in the medical record, yet it is critical for safety planning. 9 A substantial proportion of SAVs report at or after 72 hours, and they are typically adolescents. There is a high positive correlation between reporting to the police and receiving medical treatment. 10

SA is an extremely common crime, with estimates of one in three females and one in seven males being assaulted during a lifetime. 11 The mean age of the victim is approximately 20 years. She is most often single. Adolescents account for less than half of all victims seen, yet the incidence of SA peaks in the age group of 16 to 19 years. 12 For nearly 40% of victims, SA is the first sexual experience. 13 A person known to the victim commonly perpetrates the assault. Former and current boyfriends are equally common as perpetrators, lending support to the position that leaving a violent partner does not always end the terror. 9 The younger the victim, the more likely the perpetrator is to be a relative. The location of the SA varies with the victim and the type of perpetrator. In general, adults are usually assaulted in their own home, whereas adolescents are more likely to be assaulted in the assailant’s residence. 14 Stranger assaults are less common; they are more likely to involve adults, occur outdoors, and include the use of a weapon and a greater likelihood of injury. 15–18 Alcohol and drug use in both the assailant and the victim are common accompaniments to SA. 19, 20
Most assaults involve penile-vaginal penetration, and penile penetration is significantly associated with genital injury in females. Typically, digital-vaginal penetration is the second most common sexual act reported. Oral-genital contact occurs in less than 30%, with anal assault slightly less common. The use of a foreign object is unusual (10%). Anal assault is associated with increased violence, and offender preference for anal sex, and offender problems with sexual dysfunction.

Injury is not an inevitable consequence of SA. Adolescent SAVs have been shown to sustain more anogenital injuries than their adult counterparts.

Nongenital trauma occurs in 40 to 81% of SAVs, and its presence is associated with anogenital injury. The extremities are most commonly injured, followed by the head and neck. Serious injury involving hospitalization occurs in about 5%, and death associated with SA is estimated at 1% or less, although this latter figure is probably a gross underestimate. Psychological distress and interpersonal difficulties are the major sequelae after an SA. These problems are exacerbated in SAVs with known attackers who delay reporting.

**DISTINGUISHING PRINCIPLES OF DISEASE**

**Emergency Department Preparation**

A standardized approach to the management of the SAV is important. This should include, if at all possible, the development of a multidisciplinary team that works together under a protocol. That protocol should address every detail, from the handling of the SAV’s first call to dispatch to the referral for psychological support. The SAV should be taken out of the medical triage system that typifies the emergency department not only to provide privacy and security for the SAV but also to prevent the deterioration of evidence. This approach assures a consistent process of evaluation, treatment, and collection of evidence. The medical team should receive forensic training on interviewing and examination techniques; collecting, preserving, and storing evidence; and chain of custody issues. The team should be trained to use the examination form and be thoroughly familiar with the SA kit (rape kit) provided by the state or local crime laboratory. Advocates, whether provided through law enforcement or by a separate entity, need to receive training from the SART about examination procedures and staff roles so they can best advise and counsel the SAV. A SART program cannot be successful unless advocates feel that the SAV will be treated with respect and receive the best treatment available. Because the SART examiner is the first person on the medical team to greet the victim, a kind, calm, knowledgeable, and professional demeanor is of the utmost importance.

The emergency department should also be prepared for the unusual victim with significant or life-threatening injuries. In this instance, the emergency physician needs to delegate the forensic responsibility to another forensically trained staff member whose sole purpose is to collect the evidence and, if required, follow the SAV to surgery. In cases in which there is substantial injury, following the patient from intake allows the examiner to understand better and document the nature and extent of the trauma and continue the forensic process with little further distress to the patient.

**Obtaining the History and Consent**

Numerous consents should be obtained from the SAV, depending upon state and local laws. The FE should be knowledgeable about all statutes governing consent, including whether minors need parental consent. In some states, even if parental consent is not required, the FE may still be required to contact the parents and document the success or failure of this attempt. Although not part of the official consent process, most SAVs are concerned about access to the SART record and photographs, particularly when the SART examination facility is within the hospital setting. Keeping these records separate from the primary hospital chart system helps protect the privacy of the victim and has a precedent in the similar handling of psychiatric records. Surveys of SAVs have identified that they desire information about sexually transmitted diseases (STDs), pregnancy, emergency contraception, follow-up care, and physical and psychological health effects of SA.

Providing written information on these topics to the patient with his/her signature confirmation documents the patient’s receipt of follow-up recommendations. Before getting started with the history, the SAV’s immediate privacy and personal needs should be addressed. Box 64-2 outlines some of the issues that may make the interview more comfortable for the patient and ensure reliable historical information from the patient. The group taking the history may include a law enforcement officer, patient advocate, medical assistant, and FE.

A detailed history is important. California was the first state to mandate a uniform examination protocol and specific training for examiners.

---

**BOX 64-1 CONSENT ISSUES IN SEXUAL ASSAULT CASES**

**Consents Should Specify that the SAV Signature Acknowledges:**

- That hospitals and health care professionals are mandated reporters
- Receipt of information about victim compensation funds
- Specific understanding of the examination and evidence collection procedures
- Specific understanding of the use of photography in documenting physical and genital injuries
- That information collected will be sent to law enforcement and is obtainable by defense counsel
- That data without patient identity can be collected for valid educational and scientific interest
- That consent may be withdrawn at any time

---

**BOX 64-2 PRELIMINARY ISSUES AND STRATEGIES IN PREPARING FOR TAKING THE HISTORY FROM AN SAV**

- Provide quiet, confidential, safe environment.
- Briefly review the interview and examination process in private with the SAV.
- Explain sensitive/personal/embarrassing nature of questions and right to be interviewed without family or friends.
- Show concern for immediate comfort (e.g., if thirsty, take oral swabs first so SAV may drink).
- Provide advocacy.
- Always conduct interview the same way.
- Leave difficult questions until the end.
- Explain why you are asking the question and the possible responses.
- Explain that all questions must be asked.

Note: The text continues on page 806.

#### 5. Patient Information

- I understand that hospitals and health care professionals are required by Penal Code Sections 11160-11161 to report to law enforcement authorities cases in which medical care is sought when injuries have been inflicted upon any person in violation of any state penal law. The report must state the name of the injured person, the type and extent of injuries, and date and time of the assault. I understand that data without patient identity may be collected from this report for health and forensic purposes and provided to health authorities and other qualified persons with a valid educational or scientific interest for demographic and/or epidemiological studies.

**E. PATIENT HISTORY**

1. Pertinent medical history:
   - Last menstrual period
   - Any recent (60 days) anal-genital injuries, surgeries, diagnostic procedures, or medical treatment that may affect the interpretation of current physical findings? No Yes
   - Any other pertinent medical condition(s) that may affect the interpretation of current physical findings? No Yes
   - Any pre-existing physical injuries? No Yes
   - Any pre-existing medical condition(s) that may affect the interpretation of current physical findings? No Yes
   - Any pre-existing psychological condition(s) that may affect the interpretation of current physical findings? No Yes

2. Pertinent pre-and post-assault related history:
   - Other intercourse within past 5 days? No Yes
   - Other intercourse within past 5 days? Yes
   - Vaginal (within past 5 days)? When ______
   - Vaginal (within past 5 days)? No
   - Vaginal (within past 24 hours)? When ______
   - Vaginal (within past 24 hours)? No
   - Any voluntary alcohol use within 12 hours prior to assault? No Yes
   - Any voluntary alcohol use within 12 hours prior to assault? Yes
   - Any voluntary drug use within 12 hours prior to assault? No Yes
   - Any voluntary drug use within 12 hours prior to assault? Yes
   - Any pre-existing physical injuries? No Yes
   - Any pre-existing medical condition(s) that may affect the interpretation of current physical findings? No Yes

3. Pertinent pre-and post-assault related history:
   - Other intercourse within past 5 days? No Yes
   - Other intercourse within past 5 days? Yes
   - Vaginal (within past 5 days)? When ______
   - Vaginal (within past 5 days)? No
   - Vaginal (within past 24 hours)? When ______
   - Vaginal (within past 24 hours)? No
   - Any voluntary alcohol use within 12 hours prior to assault? No Yes
   - Any voluntary alcohol use within 12 hours prior to assault? Yes
   - Any voluntary drug use within 12 hours prior to assault? No Yes
   - Any voluntary drug use within 12 hours prior to assault? Yes
   - Any pre-existing physical injuries? No Yes
   - Any pre-existing medical condition(s) that may affect the interpretation of current physical findings? No Yes

4. Pertinent pre-and post-assault related history:
   - Other intercourse within past 5 days? No Yes
   - Other intercourse within past 5 days? Yes
   - Vaginal (within past 5 days)? When ______
   - Vaginal (within past 5 days)? No
   - Vaginal (within past 24 hours)? When ______
   - Vaginal (within past 24 hours)? No
   - Any voluntary alcohol use within 12 hours prior to assault? No Yes
   - Any voluntary alcohol use within 12 hours prior to assault? Yes
   - Any voluntary drug use within 12 hours prior to assault? No Yes
   - Any voluntary drug use within 12 hours prior to assault? Yes
   - Any pre-existing physical injuries? No Yes
   - Any pre-existing medical condition(s) that may affect the interpretation of current physical findings? No Yes

5. Assault-related History:
   - Loss of memory? No Yes
   - Lapse of consciousness? No Yes

6. Methods employed by assailant(s):
   - Weapons No Yes
   - Physical restraints No Yes
   - Threatened? No Yes
   - Injuries inflicted? No Yes
   - Type(s) of weapon(s) No Yes
   - Physical injuries No Yes
   - Other methods No Yes

7. Assault-related History:
   - Loss of memory? No Yes
   - Lapse of consciousness? No Yes

8. Assault-related History:
   - Loss of memory? No Yes
   - Lapse of consciousness? No Yes

9. Other methods:
   - No Yes
   - No Yes

**D. PATIENT CONSENT**

Minors: Family Code Section 6927 permits minors (12 to 17 years of age) to consent to medical examination, treatment, and evidence collection for sexual assault without parental consent. See instructions for parental notification requirements for minors.

- I understand that a forensic medical examination for evidence of sexual assault at public expense, may be conducted by a health care professional to discover and preserve evidence of the assault. I understand that the examination may include the collection of reference specimens at the time of the examination or at a later date. I understand that I may withdraw consent at any time for any portion of the examination.

- I understand that data without patient identity may be collected from this report for health and forensic purposes and provided to health authorities and other qualified persons with a valid educational or scientific interest for demographic and/or epidemiological studies.

**E. PATIENT HISTORY**

- I hereby consent to a forensic medical examination for evidence of sexual assault. _______ (Initial)
- _______ (Initial)

G. ACTS DESCRIBED BY PATIENT

- Any penetration of the genital or anal opening, however slight, constitutes the act.
- Oral copulation requires only contact
- If more than one assailant, identify by number.

1. Penetration of vagina by:
   - Penis
   - Finger
   - Object
   If yes, describe the object:

2. Penetration of anus by:
   - Penis
   - Finger
   - Object
   If yes, describe the object:

3. Oral copulation of genitals:
   - Of patient by assailant
   - Of assailant by patient

4. Oral copulation of anus:
   - Of patient by assailant
   - Of assailant by patient

5. Non-genital act(s):
   - Licking
   - Kissing
   - Suction injury
   - Biting

6. Other act(s):

7. Did ejaculation occur? Yes No Unsure
   If yes, note location(s):
   - Mouth
   - Vagina
   - Anus/Rectum
   - Body surface
   - On clothing
   - On bedding
   - Other

8. Contraceptive or lubricant products:
   - Foam used?
   - Jelly used?
   - Lubricant used?
   - Condom used?

describe type/brand, if known

---

H. GENERAL PHYSICAL EXAMINATION

Record all findings using diagrams, legend, and a consecutive numbering system.

1. Blood Pressure
   - Record

2. Exam Started
   - Date
   - Time

3. Exam Completed
   - Date
   - Time

4. Describe general appearance

5. Describe general demeanor

6. Condition of clothing upon arrival
   - Not indicated

7. Conduct a physical examination.

8. Collect dried and moist secretions, stains, and foreign materials from the body. Scan the entire body with a Wood's Lamp.

9. Collect fingernail scrapings or cuttings according to local policy.

---

Figure 64-1. Forensic Medical Report Acute (<72 hours) Adult/Adolescent Sexual Assault CalEMA 2-923 from the State of California Emergency Management Agency. This form is available at www.CalEMA.ca.gov.
I. HEAD, NECK, AND ORAL EXAMINATION

Record all findings using diagrams, legend, and a consecutive numbering system.

1. Examine the face, head, hair, scalp, and neck for injury and foreign materials.

2. Collect dried and moist secretions, stains, and foreign materials from the face, head, hair, and neck.

3. Examine the oral cavity for injury and foreign materials (if indicated by assault history). Collect foreign materials.

4. Collect 2 swabs from the oral cavity up to 12 hours post assault and prepare one dry mount slide from one of the swabs.

5. Collect head hair reference samples according to local policy.

Patient Identification

Diagram C

Diagram D

Patient Identification

Diagram E

Diagram F

J. GENITAL EXAMINATION - FEMALES

Record all findings using diagrams, legend, and a consecutive numbering system.

1. Examine the inner thighs, external genitalia, and perineal area. Check the box(es) if there are assault related findings:

   No Findings

2. Collect dried and moist secretions, stains, and foreign materials.

3. Collect pubic hair combing or brushing.

4. Collect pubic hair reference samples according to local policy.

5. Examine the vagina and cervix. Check the box(es) if there are assault related findings:

   No Findings

6. Collect 4 swabs from the vaginal pool. Prepare one wet mount slide and one dry mount slide.

7. Collect 2 cervical swabs (if over 48 hours post assault).

8. Examine the buttocks, anus, and rectum (if indicated by history). Check the box(es) if there are assault related findings:

   No Findings

10. Collect 2 anal and/or rectal swabs and prepare one dry mount slide.

11. Conduct an anoscopic exam if rectal injury is suspected or if there is any sign of rectal bleeding.

   Rectal bleeding  No  Yes

   If yes, describe: __________________________________________________

K. GENITAL EXAMINATION – MALES

1. Examine the inner thighs, external genitalia, and perineal area. Check the body for other assault related findings:
   - No Findings
   - Findings

2. Control swabs

3. Collect dried and moist secretions, stains, and foreign materials. Scan the area with a Wood’s Lamp.

4. Collect pubic hair combing or brushing.

5. Collect pubic hair reference samples according to local policy.

6. Collect 2 penile swabs, if indicated by assault history.

7. Collect 2 scrotal swabs, if indicated by assault history.

8. Examine the buttocks, anus, and rectum (if indicated by history). Check the box(es) if there are assault related findings:
   - No Findings
   - Findings

10. Collect 2 anal and/or rectal swabs and prepare one dry mount slide.

11. Conduct an anoscopy exam if rectal injury is suspected or if there is any sign of rectal bleeding.

12. Exam position used:
   - Supine
   - Other
   - Describe:

LEGEND: Types of Findings

History of Type of Sexual Assault

Questions about sexual acts need to be explicit and phrased in terms understandable to the SAV. Unless specifically asked, many victims will not disclose that injuries are a result of the assault.7 Language used by the SAV to describe sexual acts should be documented in the medical record. Importantly, the FE should ascertain if the victim voiced her lack of consent and whether that terminated the behavior. The victim’s own words should be used as often as possible and recorded in quotation marks to preserve the integrity of the interview. The experienced FE also gathers information about the sequence and type of sexual acts that occurred during an assault, including not only kissing, fondling, use of foreign objects, and digital manipulation, but also fetishism, voyeurism, or exhibitionism on the part of the suspect. Table 64-1 lists additional information, which may be useful for the investigation.

Drug and Alcohol Use

Inquiry about drug and alcohol usage is important and necessary.30,36–41 Like driving under the influence, an SA may be the first indicator that the victim has a drug or alcohol problem.42 Recent data indicate that drug and alcohol abuse by the victim is associated with a concurrent increased risk of an additional assault in the next 2 years; assaulted drug users are at risk for an escalation of drug abuse postassault.43 These victims need prompt referral for counseling and drug rehabilitation programs. Further, the use of drugs and alcohol are relevant to issues of consent, credibility, and corroboration.34,41 In the past, studies have not found a correlation between substance use and injury,13,16,21,32,46 but recent studies indicate an increase in nongenital and anogenital trauma.23 The FE should order drug screening if the victim reports loss of consciousness or forced ingestion, appears confused, is amnesic, or has other changes in physical or vital signs that are suspicious for drug use. National drug screening data from SAVs show that the prevalence of drugs used is higher among SAVs than the general population.47,48 Moreover, drugs are frequently used in combination. The two most popular combinations are alcohol and marijuana, followed by alcohol and benzodiazepines.19 Routine surveillance of drugs and alcohol is recommended.

History of Child Abuse

A history of childhood abuse increases the risk of repeat assault. Researchers now believe that identification of this vulnerable group is a prerequisite for prevention.49 The SA examination may be the one time during which the question of prior abuse is raised; a positive answer provides additional justification for referral for psychological services.

Mental Illness

About a quarter of the victims presenting for SA evaluation will have mental health problems. A history of mental illness has been shown to increase the severity of the sexual and physical attack. Moreover, the SAV often results in an exacerbation of the mental illness and higher rate of post-traumatic stress disorder.50

Prior Sexual Experience

Knowledge about the victim’s prior sexual experience is pertinent. New information has emerged that women without sexual experience are more likely to sustain genital trauma23,51 and specifically more likely to have hymenal tearing.13,21,52 Because hymenal and vaginal tears are usually associated with the dramatic presentation of bleeding, it is incumbent upon the examiner to ascertain the source of hemorrhage. The lack of visible genital injury in the female who has not had prior sexual experience does not exclude the possibility of intercourse.

SAVs are reluctant to report that they assisted the suspect in any way. Some suspects ask the victim to assist with insertion of the penis. If the SAV does this, she does so in order to avoid harming herself; this may explain the lack of the typical entry injury seen in most victims. Positioning may be another factor in the location of injury; anterior injury is more common when rear entry or female superior positions are used.22

Methods of Controlling the Victim

Much can be gleaned about the suspect from a careful interview of the SAV. Areas of interest for the examiner include the methods of approach and control of the SAV, the offender’s reaction to resistance by the victim, and the occurrence of sexual dysfunction in the suspect. While the approach to the victim is usually easy to obtain, understanding how the suspect controlled the victim may not be immediately clear, as the mere presence of the suspect may be perceived by the victim as a threat to life and result in control of the victim’s actions. Most protocols inquire about verbal threats and weapons, but getting the exact context of these (verbatim if possible) and determining whether the threats were carried out are important. Similarly, with a weapon, it should be noted whether the victim saw the weapon or whether it remained a verbal threat only. Was it a weapon of choice (brought with the suspect) or one of opportunity? Did the suspect relinquish it at any time.
or use it? The examiner should inquire into the amount and timing of the force used by the assailant along with the use of any derogatory or profane language. The examiner should inquire about strangulation; SAVs typically do not volunteer this information. Strangulation tends to occur late in abusive relationships and has been associated with a higher risk for major morbidity and mortality.53,54 The FE should take special care to ask questions in a manner that does not implicate that the victim should have done something to protect herself or to prevent the occurrence of the SA. In some cases, resistance may provoke an alternative demand, compromise, negotiation, and threat of force or use of force. If force is threatened, the examiner should be clear about whether it was used and understand how much and how long it was applied.

### Sexual Dysfunction in Offenders

Nearly 34% of convicted rapists have a sexual dysfunction, and this information is obtainable from the SAV. Sexual dysfunction includes impotence, premature ejaculation, retarded ejaculation, or conditioned ejaculation (Box 64-3). This knowledge improves the examiner’s ability to understand and collect the evidence. A premature ejaculator may have left semen on clothing or in the environment rather than intravaginally. Retarded ejaculation is associated with multiple sex acts, including anal intercourse and a more violent attack, including both genital and nongenital trauma. Serial rapists have been identified based upon language and demand for a specific order of sexual acts from several SAVs. Additionally, the SAV can be asked about any unique lesions or pathology of the perpetrator’s genitalia or other identifying characteristics.55

### Methods Used by the Offender to Avoid Detection

The FE should inquire about the methods used to avoid detection and escape, such as masks, gloves, blindfolds, or disabling the phone. An experienced assailant may also attempt to destroy evidence, such as forcing the victim to shower. Lastly, the FE should ask about missing items. Valuables or personal items retained as souvenirs have evidentiary value. The FE should ask the victim if the assailant is known to him or her; even if unknown to the victim, he or she may have a wealth of information about characteristics and behavior of the assailant.27

A complete history, which is temporally related, is crucial. The preprinted checklist forms provided by the state or local government are a good start, but unfortunately they do not elicit a specific narrative recall of events by the SAV. In every case, a dictated narrative summary is strongly recommended.

### Performing the Physical Examination and Evidence Collection

The physical examination should be meticulous and include the collection of trace evidence and reference standards (see Fig. 64-1). There is a positive association between SAV injury and the filing of charges,56 successful prosecution,57,58 and sentencing.59 In general, the sequence of observation, photography in situ, collection of evidence, and written documentation should be followed (Box 64-4). All items should be dry and placed in paper containers (no plastic), labeled (Box 64-5), and sealed. Each container should be sealed securely with tape, and the examiner should initial or sign across the tape and onto the container/bag.

To preserve the integrity of the evidence, the SAV should not be left alone in the room with it, and the FE should wear powder-free gloves to prevent contamination of the evidence. If the evidence is stored, a locked unit should be available. Preserving the chain of custody, a fundamental principle in the criminal justice system, should be understood by all personnel (Box 64-6). A complete examination and historically relevant evidence collection should be performed, irrespective of the time between the assault and examination. One investigator documents the retrieval of salivary DNA from a bite mark on a body even after the body had been submerged in water for more than 5 hours.60 The FE should not second-guess what the laboratory may or may not recover based upon rigid time frames. If there is a history of loss of consciousness or significant memory impairment, then all specimens should be collected.

### Examination of the Skin

The FE needs to describe the SAV’s demeanor and general appearance. The examiner should be especially careful to use specific terms and note responsiveness and ability to cooperate and give a history. All clothing worn during the assault should

### Documentation of Findings During Sexual Assault Examination

Findings/evidence to be documented include:
- Preexisting injuries
- Acute injuries
- Tenderness or induration
- Foreign material
- Wood’s lamp/alternate light source–positive areas
- Secretions and stains
- Potential saliva/semen (per history)
- Swab collection sites (evidence and controls)
- Indicate any site where moist swab collection occurred

### Definitions of Sexual Dysfunction Commonly Seen in Perpetrators of Sexual Assault

- Erectile insufficiency: formally impotence; difficulty obtaining or maintaining an erection
- Premature ejaculation: ejaculation that occurs immediately before or immediately after penetration
- Retarded ejaculation: difficulty in ejaculating or failure to ejaculate
- Conditioned ejaculation: able to ejaculate only after certain conditions (e.g., particular sex acts) have been met

### Information to Document on Standard Evidentiary Label

On each item in the rape kit:
- Full name of patient
- Medical record or case ID number
- Date of collection
- Time of collection
- Brief description of item with sampling site
- Initials of the examiner
be inspected, collected, and photographed. A Wood’s lamp or alternate light source should be used to detect dried secretions and to document the findings (Box 64-7).

The SAV should undress on the large square of paper from the rape kit after removing shoes. Another sheet of paper should be placed underneath this square to prevent contamination from the floor. The square paper is used to catch trace evidence and should be folded carefully and placed into evidence.

When the SAV is undressed, the FE uses the Wood’s lamp or ALS over the body and documents positive fluorescence. Dried secretions should be removed with a cotton swab moistened with sterile, distilled water. If one side of the swab is flattened and only that side is used to collect the specimen, the material is effectively concentrated. Conversely, wet secretions should be taken in the same manner using a dry swab. Swabs should be taken from areas of contact indicated by the SAV, even if there is no fluorescence or crusting seen. A double swab technique is used to collect saliva from skin (Box 64-8). Bite marks need special attention (Box 64-9). Control swabs should be taken in areas adjacent to the material removed and labeled as such. All swabs should be dried in a stream of cool air at least 60 minutes before packaging. Swab-drying machines are available with locks to facilitate this process. To prevent contamination, only one person’s evidence should be in the dryer at a time, and the drying chamber should be cleaned after each use with a 10% bleach solution. The location of all foreign material should be documented on the body diagrams and packaged in the standard fashion. Fingernail clippings or scrapings should be collected according to local custom and only if there is historical relevancy. All preexisting injuries and acute trauma need to be documented in the report.

Diagrams of the body should be large enough to allow documentation to remain clear. If need be, copies of the state/local diagrams should be available in full-page format to accomplish this. The documentation process in some states is artistic, which means the FE draws the injury on the diagram. California has switched to a purely descriptive approach for uniformity and clarity (see Fig. 64-1).

**Head, Neck, and Oral Cavity**

In examining the head, neck, and oral cavity, special attention should be given to the integrity of the frenula, buccal surfaces, gums, and soft palate. The SAV should not be allowed to eat or drink before this examination. If the SAV gives a history of oral copulation with ejaculation, then the upper and lower lips should be wiped using two moistened swabs. Next the examiner should swab from the gum to the tonsillar fossa, the upper first and second molars, behind the incisors, and in the fold of the cheek. If more than one swab is used to swab these areas, each should be labeled appropriately. Lastly, using a 16-inch piece of unwaxed floss, with two knots tied about 2 to 3 inches apart in the center of the floss, the SAV should floss her teeth using only the section between the knots. While flossing, the patient should lean over a clean 8 × 10 piece of

---

**BOX 64-6** CHAIN OF CUSTODY

Record of signatures, dates, and times that:
Document handling, transfer, and storage of evidence from the time of collection
Provide sequential accountability of everyone who handled the evidence
Document the location of the evidence at all times
Ensure there has been no tampering, alteration, or loss of evidence prior to trial
For all transfers of evidence, documentation should include:
Signature of person transferring custody
Signature of person receiving custody
Date of transfer
Time of transfer
Documentation is written on sealed and packaged kit

**BOX 64-7** WOOD’S LAMP AND ALTERNATE LIGHT SOURCE (ALS)

**Wood’s Lamp**
Screening tool for detection of stains, secretions, and injuries
Long-wave UV light (310–400 nm)
Dried semen will usually fluoresce bright green/yellow or white
Moist semen fluoresces poorly or not at all
Other body fluids and substances may be seen
Room must be dark to use

**ALS**
High-intensity, tunable light source
Uses four narrow bands: 450, 485, 525, and 570 nm
Two wide bands: white light, all wave lengths <530 nm
Colored goggles used to block the reflected light and pass only the fluorescent light
Because of absorptive differences between normal and damaged tissues can detect injuries not seen with the naked eye
More accurate for certain body fluids and substances than Wood’s lamp

**BOX 64-8** DOUBLE SWAB TECHNIQUE FOR THE RECOVERY OF SALIVA FROM HUMAN SKIN

First swab: completely wet with sterile distilled water
Roll over the surface of the skin using moderate pressure and circular motions.
Rotate swab on long axis to assure maximal contact.
Air dry completely (≥30 min).
Second swab: used dry
Apply with the same action as above to pick up all the moisture left behind.
Allow to dry completely (≥30 min).
Label each and submit with other evidence.

**BOX 64-9** COLLECTION OF BITEMARK EVIDENCE

Take an orienting photograph before swabbing. Then be certain to take close-up photographs, and use a scale if the bite mark is on a rounded surface, you will need more than one photograph to avoid distortion. Notify law enforcement immediately, so that they can contact a forensic odontologist who may take additional photographs and collect impressions. Serial photographs are recommended at 24-hour intervals for up to 5 days. Use the double-swab technique to obtain saliva sample.
paper to catch any debris. The paper and floss are dried and bundled together. If the SAV is unable to use the floss, the examiner, wearing gloves and goggles, can perform this procedure.65

Hair matted with secretions or debris should be cut out and packaged. Signs of manual or ligature strangulation may include neck injuries with petechiae of the skin and conjunctiva. Reference samples for head hair and saliva should be taken according to local custom, including buccal swabs made for DNA analysis. Reference standards are used to determine whether the evidence specimens are of victim origin or are foreign. Additionally, they may help identify or eliminate potential suspects.

**Anogenital Examination**

The anogenital examination should begin with gross visualization of the inner thighs, external genitalia, and perineal area and anus, followed by Wood's lamp or alternate light source visualization. All trauma, secretions, and foreign material should be noted and appropriately handled. Gross visualization yields positive findings in 20 to 30% of cases (range 5–65%).11,28,30,51,52,56,64 Genital trauma associated with SA is considered to be a mounting injury because it occurs at the point of first contact of penis to vagina. This area, the posterior fourchette (soft tissue) or the perineal body (the junction of the tendons of the superficial transverse perineal and the bulbocavernous muscles) is inherently weak, and continued pressure will result in tearing. The position of restraint, male straddling female, will also effectively prevent the victim from accommodating the erect penis. The angle of the erect penis is not the same as the angle the vagina makes with the vestibule (approximately 45 degrees). Moreover, the vagina is considered a potential space. The lateral walls are more rigid than the anterior and posterior walls, so that in its normal state the anterior wall is collapsed onto the posterior wall; hence the use of the speculum to lift the anterior wall during the gynecologic examination.66 During voluntary intercourse, the changes that occur with sexual stimulation, the human sexual response, remove these normal anatomic barriers and the female voluntarily tilts her pelvis.66

Typically, genital injury involves more than one site, is external, and is located posteriorly between 3, 6, and 9 o'clock (Fig. 64-2). The posterior fourchette is the most common site of injury.11,13,21,22,52 Injuries are usually the result of blunt force trauma, which produces tears, ecchymosis, abrasions, redness, and swelling. The latter two may be difficult to recognize without a follow-up examination, and some investigators have suggested not reporting redness or swelling if a second examination is not performed.13 Hymenal trauma is not the first site of injury, as myth would have it. Hymenal trauma is more common in adolescents and those without sexual experience.13,22,51,52

Genital injury shows consistent topologic features, varying with the site and nature of the tissue. Tears are most commonly seen in the posterior fourchette and fossa navicularis. Abrasions typically occur on the labia minora. The hymen usually sustains damage in the form of ecchymoses or tears.21,22

Many factors affect the prevalence of genital injury, and the FE should be familiar with them (Box 64-10). Even though genital injury is statistically significantly associated with a history of nonconsent, the FE should not forget that genital trauma is not inevitable. Colposcopic magnification should be employed to photodocument these areas and to better identify the type of trauma seen. Colposcopy has been the standard of care and is the best method for determining genital injury.67,68 Currently, many centers are using digital photography and videography with excellent results and less cost. Certain environmental factors have been identified with colposcopically recognized genital changes; this is particularly true with intra-vaginal findings (Table 64-2).69 Frequently, trace evidence is seen only with the coloscope. We use adhesive note paper (Post-It) to capture such tiny particles while visualized under the scope. The Post-It is then folded and inserted into an envelope. Examiners should check with their local crime laboratory to see if this methodology is acceptable. Pubic hair brushings are collected by placing a sheet of paper under the patient’s buttocks and brushing the pubic hair downward. The paper and brush should be bundled together and packaged. A pubic hair standard may be obtained according to local custom.

A warm speculum moistened with water should then be inserted into the vagina. Inspection of the vagina and cervix should be performed first grossly, then with colposcopic

photography. If the SAV reported bleeding, the source needs to be determined. Bleeding is commonly associated with hymenal, vaginal, or combined tears. Swabs from the vagina and cervix should be obtained, air-dried for 60 minutes, and packaged. Cervical specimens augmente those from the vaginal pool because the cervix acts as a reservoir and provides evidence of seminal products for longer periods of time (Table 64-3). To check for motile sperm, the FE should inspect a wet mount slide. This method is useful because it gives a time frame for the assault, and sufficient numbers of sperm (60–100) allow for identification of a suspect. Semen is found about 50% of the time. The FE should communicate this information to the investigator as soon as possible. The wet mount slide is then dried and prepared for deposit into the rape kit. Aside from time and site of deposition, female and male factors influence the ability to find semen (Table 64-4). Typically, a bimanual examination is not performed.

- A rectal examination is performed if indicated by the history. Because SAVs are reluctant to report this type of activity, however, the FE should always inspect the anus for signs of injury and reinquire about anal contact. Asking the patient to bring her knees up to her chest allows this examination to be done easily and quickly. If trauma is seen or the history suggests anal penetration, rectal bleeding, or that a foreign object was used in the assault, a rectal examination, including anoscopy, should be performed. To avoid contamination with vaginal secretions, the perianal region is swabbed thoroughly with a moistened swab or 2 × 2 gauze, which is dried, labeled, and included in the rape kit. This procedure should be done after all vaginal samples, external secretions, and foreign material have been collected. A warm water–moistened anoscope is used to perform the procedure. The examiner observes grossly, colposcopically, and photographs are taken. Swabs are collected under direct visualization beyond the tip of the scope. The source of any bleeding needs to be determined.

### Special Staining Techniques

The use of special staining/lubrication techniques should be reserved until all photography and specimens are collected. On areas that are painful, 2% lidocaine gel can be used to obtain better visualization and pictures. Toluidine blue dye is a nuclear stain that has been shown to enhance gross visualization of external genital (vulvar) injuries (Fig. 64-3). Toluidine blue dye has some spermicidal activity and was shown, in one small study, not to influence DNA analysis. Stain results depend upon the presence or absence of a nucleated cell population at the exposed surface. Positive stain results can be seen with trauma, cancer, and areas of inflammation with a nucleated cellular infiltrate. Acutely, with tissue swelling and transudation, the dye may lift off quickly. Twenty-three categories of benign disease, along with columnar epithelium, and mucus will take up this stain. Toluidine blue dye is nonspecific and should be used to enhance trauma seen with the colposcope or as an adjunct for gross visualization. It should not be used to date injuries. Diffuse staining or patchy uptake should not be reported. Uptake should not be reported when no findings are seen with colposcopy.

### Photographic Documentation

Photodocumentation has become the standard of care. It eliminates the problem of hyperbole and understatement in the FE’s description and allows the court to see a visual representation of findings on examination. Importantly, photodocumentation makes each case available for peer review and consultation, alleviating the need for repeated examinations by defense experts. The entire examination should be photographically documented if at all possible, not just the positive findings. All photographs should be correctly labeled to show patient identification, date, time, and examiner. Frequently this information can be combined with a color guide and ruler. Jurors usually want to know how pictures are identified. The FE should develop a standard photographic technique, making certain that the plane of the film is parallel with the injury to minimize distortion. Photos of skin are enhanced if the background is blue or green because the automatic lens adjusts according to the lightest part of the picture. The examiner should take pictures of lesions first without magnification, then take closer views as needed. The full extent of the injury needs
to be captured. Using magnification usually requires more than one shot. The examiner should take many pictures because he or she has this opportunity only once (Box 64-11 outlines tips on performing photographic documentation in SA cases). Pictures are also a concern for SAVs. Most SAVs worry about where the pictures are kept and whether their name will appear on the pictures. Keeping the SART record separate from the medical record is reassuring. Some groups go a step further and separate the pictures from the written reports.

**SEXUALLY TRANSMITTED DISEASES AND PREGNANCY**

The risk of acquiring an STD after an SA is small but will vary by region and number of assailants (Table 64-5). Testing for STDs is expensive, requires a reassessment of the patient, which is often difficult, and has no forensic value. Most protocols no longer require or pay for this type of assessment. Additionally, many SAVs have preexisting STDs. Most providers prefer preventative therapy (Box 64-12) and it offers the SAV the psychological benefit of immediate protection from infection. For updated information and alternative therapies for patients who are pregnant or have specific allergies, the physician can consult www.cdc.gov and enter “std treatment.” The efficacy of these regimens in preventing gonorrhea, trichomoniasis, bacterial vaginosis, and *Chlamydia trachomatis* genitourinary infections after SA has not been evaluated. The FE should counsel patients about the possible toxicity of any regimen; gastrointestinal problems are especially common, and the FE should consider antiemetic medication, particularly if emergency contraception is also prescribed. All patients should be advised to abstain from alcohol for 24 hours after metronidazole use and from sexual intercourse until the treatment is completed.

### Hepatitis B

Hepatitis B vaccination, without hepatitis B immune globulin, is recommended for those SAVs who are unimmunized (Box 64-13). Risk factors for hepatitis B virus include multiple sexual partners (more than one sex partner in a 6-month period), a recent history of an STD, men who have sex with men, correctional facility inmates, and intravenous drug users. Currently, testing to determine antibody levels in immuno-
The FE should give the vaccination even if the completion of the series is not assured. Note that some protocols may not cover this cost. Costs may not be covered by local protocols, and postexposure prophylaxis needs to be provided in the context of a comprehensive counseling, treatment, and follow-up program. To maximize the likelihood of success, therapy should be initiated as soon as possible or up to 72 hours following the assault, so that expeditious referral is prudent.

Assistance with postexposure prophylaxis decisions can be obtained by calling the National Clinician’s Post-Exposure Prophylaxis Hotline (PEPLine), telephone: (888)-448-4911.

**Follow-up Testing**

For SAVs who do not want postexposure prophylaxis, repeat HIV testing is recommended at 6 weeks and 3 and 6 months. If a suspect is apprehended, HIV testing can be done with his consent or a blood sample held and tested at a later date after a court order has been obtained on the victim’s behalf. Some states permit testing of the suspect at the victim’s request in cases of SA. Many protocols do not require serologic testing and do not cover this cost.

**Pregnancy Prophylaxis**

There is a 2 to 4% risk of pregnancy from random unprotected intercourse; this figure reaches nearly 50% in women 19 to 26 years old, who are at their most fertile period, when combined with midcycle exposure. Before any medication is given to an SAV, pregnancy testing should be done. This includes patients already taking oral contraceptives, those fitted with an intrauterine device, or those who have undergone tubal ligation. The immediate use of an emergency contraceptive can reduce the risk of pregnancy to 1 to 2%. Its effectiveness depends on the regimen used and the time interval between exposure and treatment (Table 64-7). Data show that an emergency contraceptive should be offered up to 5 days after unprotected sex. There are no absolute contraindications to the use of hormonal emergency contraception, even for women who have contraindications to the long-term use of combination hormonal contraception. In those who have active migraine headaches with neurologic symptoms or a history of stroke, pulmonary embolus, or deep vein thrombophlebitis, prostestin-only emergency contraception or the insertion of an intrauterine device should be considered first. The latter device offers the advantage of up to 10 years (depending on the device) of effective contraception. Evidence suggests that there is not an increase in ectopic pregnancy with emergency contraceptive

use. Although there are no studies large enough to quantify the teratogenicity of hormonal emergency contraceptives, no increase in birth defects has been detected among infants exposed to daily oral contraceptive use.85–88

### DEBRIEFING

Regardless of any physical injury, psychological distress is always present following an SA, and the FE needs to acknowledge that from the beginning of the examination. Establishing a quiet and calm place for the examination and evidence collection reassures the SAV and gives back to her a sense of control and safety. At the termination of the examination, the FE should spend time reviewing the physical and genital injuries and address modes of therapy as appropriate. The examiner should discuss any pending laboratory data and how results will be communicated (phone, written, or both) with the SAV. The method of communication should be acceptable to the SAV. The examiner should review all medication and vaccinations (e.g., tetanus), discuss side effects, and provide contact phone numbers in case of problems or questions. The examiner should review the common psychological problems (Box 64-14) and reinforce the need for counseling. The advocate who has been present during the examination can be a personal contact already established with the SAV. Nonetheless, contact numbers for rape crisis, local crisis intervention, social services, drug and alcohol services, HIV services, and emergency psychiatric services should be reviewed in detail, and all referrals should be discussed prior to departure. Compensation for victims of crime should be discussed and appropriate referrals made.

A forensic follow-up examination of all patients with genital injury should be scheduled.83,89–91 This examination is particularly important for SAVs with genital injury. It documents the healing of injury and differentiates those findings that can be confused with trauma, such as hypervascularity, telangiectasia, and cherry red spots.22,79 Its utility extends to nonspecific injuries such as swelling or redness, which are difficult to detect and create frequent interobserver disagreements.13 This examination also gives the FE an opportunity to review any problems and encourage counseling, if it has not already begun. All of these plans should be in written format because most SAVs do not remember what is said during a time of crisis.

### BOX 64-14 RAPE TRAUMA SYNDROME

#### Acute Phase
- Expressed Crying
- Anger
- Restlessness
- Controlled Calm, quiet
- Emotionless
- Somatic and emotional reactions are prominent
  - Increased muscle tension
  - Headaches
  - Genitourinal disturbances
  - Fear/guilt
  - Fatigue
  - Gastrointestinal disturbances
  - Anger/self-blame

#### Outward Adjustment Phase
- Alteration of daily routines
- Change of residence
- Change of phone numbers
- Seeking family support (often without giving reason)
- Fears and phobic reactions
- Daytime anxiety
- Nightmares

#### Integration Phase
- Survivor accepts the rape as part of her life
- Survivor begins to integrate the crisis into her life experiences

### ELDERLY VICTIMS

Two to six percent of all SAVs are over 50 years of age. The risk of being sexually assaulted or physically assaulted is further increased for homeless women in this age group.92 Older women are less likely to report sex crimes due to self-blame and humiliation. The asexual stereotype attributed to them by family, caretakers, and other professionals often prevents detection. While most elderly SAVs present within 72 hours, delayed reporting is seen. This is especially true when the perpetrator
is a caregiver. In 2005, A Perfect Cause, advocates for disability and elder rights, documented that 795 registered sex offenders were living in long-term care facilities and 5 were employees. Elder SAVs present unique challenges to the FE. The history should be expanded to include medical problems, medications, surgical procedures, history of dementia, and neurologic problems. Obtaining the history may be difficult. Some patients may present in a disorganized state without a diagnosis of dementia. Others may have hearing impairment, cognitive disabilities, or psychiatric disturbances; the latter conditions, considered important vulnerabilities, often require special interviewing skills, and the examiner may need to obtain the history from other reliable sources. Positioning should be thoughtfully performed with regard to limitation of motion for both natural and artificial joints and the need to prevent cardiovascular problems that attend anxiety and stress in this frail population. Skin changes related to aging, infection, and trauma can be difficult to discern, and a follow-up examination, including photodocumentation, will help to resolve these important issues. Bruising not may be seen initially.

Usually the SAV lives alone and the assault occurs at her home; the assailant is almost always a stranger. Sexual dysfunction and substance use are commonly seen in these perpetrators, and robbery is often involved. The most common type of assault is penile-vaginal intercourse, and genital injury is more frequent and severe than in younger SAVs, requiring hospitalization and even surgery. Clinically, lacerations, abrasions, and edema to the perineum and vagina are present. Physical restraint is common and usually in excess of what is required for restraint. The aftermath of assault is particularly devastating for this age group. Older adults have high morbidity and mortality rates, even when they have sustained relatively minor injury; this may be attributed to concurrent medical conditions, decreased physiologic reserve, or adverse reactions to and between medications. Psychologically, post-traumatic stress with subsequent illness is more frequent and severe than in younger SAVs, requiring hospitalization and substance use.

#### MALE VICTIMS

Male SA is vastly underreported. Most victims seen come from institutional settings, with very few indeed from the nonincarcerated population. Factors that act as barriers to reporting this crime include societal beliefs that a man can defend himself and fear that his sexual orientation is suspect. The need to maintain emotional control makes disclosure very stressful. Men need to be accorded the same sensitivity and support as their female counterparts.

Except for their anatomic differences, the procedures for the history, physical examination, evidence collection, and medical treatment are the same. Certainly, because of the typical location of injuries, some researchers have emphasized the increased risk of exposure to HIV, hepatitis B, and hepatitis C. Some notable differences in the assault characteristics from those seen in female victims include a predilection for anal and oral sexual contact, with subsequent injury seen in 50 to 67%, more common use of the prone position during the assault, a higher incidence of nongenital trauma (80% in one study), use of a weapon, assault by a stranger or multiple assailants, and a history of abduction. Injuries to the penis and scrotum occur less often and may be the result of a non-sexually related injury (e.g., kicks). In one study, the use of colposcopy, in addition to anoscopy, allowed the discovery of increased physical examination findings in men. As with female SAVs, colposcopy is recommended because of its additional utility for photodocumentation and collection of trace evidence.

---

### MALE SUSPECT EXAMINATION

The importance of the male suspect examination should not be overlooked. The SAV and suspect are the two pieces of the forensic puzzle in an SA. If they are evaluated and treated in the same location, it is critical that they not come in contact with each other. Expectations about this examination should be tempered by the FE’s knowledge of the suspect’s rights and the time elapsed between the assault and the examination. Presumed innocent, the suspect should be handled with the same courtesy and respect as any other patient.

If the FE is the same for both SAV and suspect, the examination is facilitated by the examiner’s knowledge of the SAV’s history. If a different examiner is used, he or she should know the history as given by the victim, and this usually can be obtained from law enforcement. The history obtained from the officer is not the history that is recorded on the suspect evaluation form. The history on the examination form should come from the suspect, but he has the right to remain silent on the events surrounding the assault. If, after understanding his rights, he chooses to give information about the events under inquiry, the examiner should have him sign the consent and record his statements on the suspect form. Most suspects will voluntarily give this information. For suspects in custody, the consent is not necessary because state law provides for the collection of perishable evidence. The FE should be knowledgeable about local laws, and a protocol should be developed to handle suspects who resist the collection of evidence. The interview and examination, for security reasons, are performed with law enforcement present at all times. The FE needs to record suspect statements verbatim, using quotation marks just as is done with the SAV. Medical information about pre-existing conditions and hygiene is focused upon factors that could influence interpretation of current findings. If there is a history indicating the possible transfer of biologic material between the SAV and suspect, appropriate specimens should be collected irrespective of hygiene or timing.

The physical examination follows the same format as the SAV examination. Injury to the suspect occurs less often than to the SAV; however, swabs of the penis, including the glans, shaft, base (but excluding the urethral meatus), scrotum, and sulcus of the foreskin, if present, are taken. In contrast to the SAV examination, identifying features such as tattoos and scars should be noted and documented photographically. Reference samples, including blood, saliva, and hair, should be taken in accordance with local protocol. Typically, STD cultures and serology are performed, although they may not be required or paid for in current state protocols, and information about pending results and treatment is given as indicated.

---

### KEY CONCEPTS

- The role of the FE is to provide a thorough examination as the basis for a report.
- Physical examination findings should be accurately, reliably, and clearly documented.
- The SAV should be offered emergency contraception and prophylaxis for sexually transmitted infection, including hepatitis B and in select cases HIV.
- Ultimately, the FE should be able to report findings and medical information in an understandable format for the court.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Emergency medical specialists, by nature and by necessity, focus their problem-solving skills on the presenting health complaint or bodily symptom that motivated the patient to seek relief at that particular moment. In the case of intimate partner violence (IPV), such focus may lead to blinding tunnel vision and missed opportunity to lift the veil of shame and empower a victim to consider options to reduce future harm and restore emotional and physical well-being. Most physicians, especially the younger ones, consider partner violence in the differential diagnosis of a physically injured woman. IPV is a shame-based disease not readily disclosed or discussed with the health provider, let alone anyone else. Patients who present acutely with an IPV injury represent the “tip of the iceberg.” Emergency physicians are probably treating many more victims of IPV who present for other problems that may actually be comorbid to IPV or are complications of prior physical, sexual, or emotional abuse. The portion of the iceberg beneath the water level is the most dangerous—the breadth of its menace is difficult to ascertain, yet the urgency to safely navigate the turbulent waters is paramount. The intent of this chapter is to educate emergency medicine specialists about the health problem of IPV so that they can move beyond the obvious and improve IPV identification, facilitate earlier intervention, and reduce morbidity and mortality for victims and their children.

**Epidemiology**

**Definition and Types of Intimate Partner Violence**

In 2002, the World Health Organization (WHO) declared that "violence is a leading, world-wide public health problem" and then further declared that violence is not an intrinsic part of the human condition and it can be prevented. Gro Harlem Bruntland, the Director General of the WHO, wrote, “to many people, staying out of harm’s way is a matter of locking doors and windows and avoiding dangerous places. To others, escape is not possible. The threat of violence is behind those doors—well hidden from public view.” The WHO report distinguishes three general categories of violence—individual, interpersonal, and collective—and then further divides interpersonal into familial or stranger violence. IPV is a form of interpersonal, familial violence (Fig. 65-1).

Intimate partner violence has been defined by the Centers for Disease Control and Prevention (CDC) as the threat or infliction of physical or sexual violence by a current or former adolescent or adult intimate partner or spouse. This violence is often accompanied by psychological abuse. The physical, sexual, and psychological forms of IPV occur as a pattern of assaultive and coercive behaviors. Physical violence consists of behaviors such as pushing, hitting, slapping, punching, kicking, biting, burning, strangulation, using objects and weapons, and controlling access to health care, medications, food, or shelter. Sexual violence includes behaviors such as forced sex, coerced sex with a partner or other persons, violence in association with sexual assault and rape, preventing the use of birth control, and refusing to use condoms to prevent the transmission of sexually transmitted infections and HIV. Psychological abuse includes behaviors such as intimidation, degradation, humiliation, isolation from family and friends, violence or threats of violence against family members, stalking, attacks against pets, destruction of property, controlling access to food, shelter, clothing, transportation, and money, and controlling employment and social or professional activities.

In the past, IPV has been referred to by a number of different terms. These include domestic violence, spouse abuse, wife abuse, battering, battered woman, and wife beating. However, the use of the term intimate partner violence is recommended as it is a more inclusive term and applies equally to adolescents and adults, females and males, opposite- and same-sex intimate partners, married and unmarried individuals, and current and former intimate partners.

State penal codes may utilize slightly different definitions of IPV from those of the CDC, especially as pertain to the nature of the relationship between the two individuals, and the forms of abuse that have transpired. In addition, the term domestic violence is generally used by the criminal justice system when referring to partner violence.

**Prevalence**

There are numerous population-based and health care–based studies that report prevalence rates of IPV victimization. Due to the different types of IPV (i.e., physical, sexual, psychological/emotional), the pattern of the violence (i.e., first episode, ongoing, intermittent, previous experience), and the population being surveyed, the reported IPV victimization prevalence rates vary widely. The prevalence of IPV victimization is often expressed as either a 1-year prevalence (the proportion
of the population experiencing IPV in the past year) or as a lifetime prevalence (the proportion of the population who have ever experienced IPV). In order to fully understand the meaning of reported IPV prevalence rates, or to be able to compare IPV prevalence rates between studies, one should look at the population being studied, the types of abuse being measured, and the period of time being studied. The variation in research methodology between studies makes IPV surveillance challenging. In an attempt to improve IPV surveillance, the CDC published recommended uniform definitions and data elements for IPV research.2

The National Crime Victimization Survey (NCVS) and the National Violence Against Women Survey (NVAWS) are two large population-based surveys. In the NCVS, a randomized telephone survey of 42,000 households and 76,000 males and females 12 years and older, 20% of violent crime against women was IPV and 85% of IPV victims were women.3 In the NVAWS, a random telephone survey of 8000 men and 8000 women 18 years and older, 22% of women and 8% of men reported being physically or sexually assaulted by an intimate partner during their lifetime; 1.5% of women and 0.9% of men reported being physically or sexually assaulted by an intimate partner within the previous year.4 According to the NVAWS, women in same-sex relationships reported lower rates of IPV (11%) than women in opposite-sex relationships (20%). On the other hand, men in same-sex relationships reported increased rates of IPV (23%) compared to men with female partners (8%).5

The prevalence rates of IPV among emergency department (ED) patients are greater than those of population-based studies. While numerous IPV prevalence studies have been conducted in the ED, they are difficult to compare due to differing methodologies. The majority of ED-based studies have examined IPV prevalence rates among women. In general, ED-based studies report the incidence of acute abuse, 1-year, and lifetime prevalence rates. Based on several ED-based surveys, 1 to 7% of all adolescent and adult females who presented to the ED did so on account of an acute episode of physical abuse.6 Moreover, 14 to 22% of all female patients in the ED disclosed that they had experienced IPV in the prior year.7,8 The lifetime prevalence of IPV among female ED patients may be as high as 54%.9 Few studies have investigated the prevalence rate of IPV among male ED patients, and those that did did not consider whether the relationship was homosexual or heterosexual IPV, did not specify whether injuries were sustained in the course of partner retaliation, defense, or retribution, and did not differentiate the force used and nature of injuries sustained.10,11 The chief concern in comparing male and female victimization is that the dynamics of the abuse may be very different.

Health care providers (HCPs) will care for fatal or near-fatal cases of IPV in the ED, although the relationship between the victim and perpetrator may not be apparent at the time. Two studies found that up to 43% of female homicide victims had presented to an ED within the 2 years prior to their deaths.12,13 According to the Federal Bureau of Investigation, 60% of fatal IPV victims are women, and 34% of women are killed by an intimate partner.14 Unfortunately, in most homicide cases, the relationship between victim and perpetrator is never determined.

Finally, the annual economic cost to society in the United States is estimated at $8.3 billion dollars, in 2003 U.S. dollars, for direct medical and mental health services as well as lost productivity.15 In one study, Wisner found that women patients experiencing IPV cost their health care plan $1775 more annually compared with the general female enrollees.16 Other studies found that women patients with documented IPV have higher health care utilization and costs than those without IPV.17,18 Rivara’s research showed that even 5 years after abuse, IPV patients’ health care costs were 19% higher than those of nonabused women.19 Further, higher health care utilization and costs were seen in children whose mothers experienced IPV, even if the abuse ceased prior to their birth.20

**Risks for Victimization**

A few individual factors have been identified that appear to place persons at risk for IPV victimization: gender, age, exposure to violence in family of origin, use of alcohol, and being physically or mentally disabled. Most victims of IPV are young women, usually less than 35 years of age,21 and single, separated, or divorced. Violence in the family of origin, such as witnessing IPV between caretaking adults, is one of the primary risk factors for victimization.22–24 but direct childhood physical or sexual victimization also has been linked with adult IPV victimization.25 Alcohol use also plays a role in both victimization and perpetration of violence, probably due to its disinhibitory effects. In Caetano’s study, 30 to 40% of men and 27 to 34% of women arrested for IPV perpetration were drinking at the time of the event.25 If men were drinking at the time of the physical assault, female victims were more likely to sustain a serious physical injury.26,27 Victims with disabilities appear to experience rates of physical and sexual abuse rates greater than or equal to women without disabilities.28

Other factors appear to contribute to the risk for IPV either because they contribute to relationship stress or they heighten victim vulnerabilities. IPV appears to occur at increased rates among relationships with lower socioeconomic status, where the abuser is unemployed or of lower levels of academic achievement.29–32 Homeless women, in general, have higher
cumulative rates of violence over a life span than women with stable housing and fleeing domestic violent homes has been noted to be one of the causes of homelessness in women. Immigrant women are another vulnerable population, and while IPV may not be occurring at higher rates among this group than in the native population, they may be reticent to disclose IPV, fearing deportation of themselves and/or their spouse. Immigrant women may be further isolated from services due to language barriers, lack of social support, or lack of economic independence.

Certain presentations should provoke consideration of IPV as an underlying or comorbid condition. One presentation is the woman with injuries to the head, face, or neck. According to a study by Ochs, a woman with head, neck, or facial injury as an underlying or comorbid condition. One presentation is of economic independence.

Another presentation that should prompt consideration of IPV is the female patient who has attempted suicide. Abbott found that among female patients with a lifetime history of a suicide attempt, 81% also had a history of IPV. Over 90% of women hospitalized following a suicide attempt reported current severe IPV. In addition, Abbott found that among women patients who abused alcohol, 71% also experienced IPV.

Finally, Warshaw found that 67 to 83% of HIV-positive women patients in a hospital clinic had male partners who were abusive and refused to use condoms.

**Risks for Perpetration**

Most of the research on persons who abuse their intimate partner is done on men who have committed violence of sufficient severity to have been arrested. While batterers are a heterogeneous group, some researchers have postulated three typologies: (1) the borderline/dysphoric, (2) the antisocial generally violent, and (3) the family only, no psychopathology. The men in the first group, “borderline/dysphoric,” are often described as both charming and moody with “Dr. Jekyll–Mr. Hyde” personality changes from one extreme (complacent) to another (rageful). High rates of alcohol and drug use appear in this group, as well as increased contacts with police for violent or disorderly conduct offenses, and increased concerns about rejection or abandonment. The antisocial generally violent male is described as “self-centered, self-absorbed and lacking in empathy.” Intimate partners are viewed as objects or possessions that serve the perpetrator’s needs. While he may appear confident and exciting, he also manipulates and imposes his values on others. Antisocial batterers usually commit both physical and sexual violence that is more severe than the other two types, as well as committing more violence outside the family. The third type is composed of men described as the “guy next door,” not violent outside the home but usually with evidence of passive dependency or obsessive-compulsive personality style. They are rigid, rule bound, and conventional, and any deviation from “the rules” can become internalized resentments that occasionally erupt in aggressive outbursts of hostility and violence.

Other factors seem to have some association with IPV perpetration: younger age, lower socioeconomic status, exposure to violence in the family of origin, alcohol abuse, history of traumatic brain injury (anger flares and poorer impulse control), and highly or abnormally spouse-specific dependency.

**Risks to Children Living in Intimate Partner Violence Homes**

In one study of police responses to IPV, about half the women reported that their children witnessed the violence. In another study of police calls, police or IPV advocates documented that children had witnessed the assault in 76 to 85% of the cases. Younger children appear to be more likely to be exposed to the violence, because older children leave when they sense escalation of tension in the home. Children initiate calls to police in about 10% of IPV emergency calls.

Children who live in IPV homes can suffer physically and emotionally, and the health impact can be acute or can lead to long-term health risks. The risk of exposure begins in the prenatal period. Pregnant women who are abused are more likely to smoke, consume alcohol, and use illicit drugs than nonabused pregnant women. Pregnant women who experience IPV physical abuse experience miscarriage, premature rupture of membranes, preterm labor, and placental abruption at higher rates than pregnant women who have abdominal trauma due to other causes.

Children in IPV homes are at increased risk for direct physical abuse by the IPV abuser and less often by the IPV victim. Some state child welfare data have demonstrated that IPV appears to be associated with the most severe and fatal cases of child abuse. Children can also be caught in the crossfire, and one study showed that small children are injured while being held in their mothers’ arms while older children get injured during their attempts to intervene.

Of great interest is the neurobiologic impact of exposure to violence at a young age. It has been demonstrated that chronic stress can cause the emotional, more primitive parts of the developing infant or toddler brain to become overly active or reactive to the environment. Stress can affect myelination and synaptogenesis and can result in problems in learning, memory, and behavior.

HCPs who care for victims of violence should recognize the interrelated nature of various forms of violence and abuse. In the case of IPV, when an adult victim is identified, an assessment of the well-being of children should also be done. If the HCP suspects a child is being neglected or physically or sexually abused, there is a good chance that IPV is also occurring. Intervention programs should be prepared to address the health and safety needs of both child and adult victims that may co-occur in one family. Exposure to violence and abuse is a health risk factor that should be routinely addressed in a primary care practice, and emergency HCPs will encounter high rates of exposure in ED pediatric patients. Clinicians should interview older children alone and younger children in the presence of a guardian. Children’s medical records can be sealed by court order from a guardian parent if the physician can document sufficient concern for the health and safety of the child.

**Special Considerations for Adolescents in Abusive Relationships**

In a nationally representative sample of 7500 adolescents who responded to the National Longitudinal Study of Adolescent Health, 12% reported an experience of physical violence in an opposite sex relationship in the previous 18 months. If the question included sexual, physical, or psychological abuse, the rate rose to 32%. In a 2005 survey conducted by the CDC, 9.2% of male and female high school students reported an
one episode of dating violence in the preceding year.64 Higher rates are found in rural populations and when youth from lower socioeconomic groups were surveyed.65,66 Surveys show that boys and girls both report acts of physical aggression; however, girls report more serious acts such as strangulation or use of a weapon in the assault or rape.67–70 Girls are more likely to be worried or scared of relationship violence, while boys minimize the psychological impact of the aggression; however, this may be more of an enculturated response than a true reflection of boys’ anxiety.71 Complicating understanding regarding prevalence of relationship violence in teens is the fact that in some states it is reported as child abuse and in others as IPV.

Pregnant teens seem to be a high-risk population for prior exposure to violence. In one study of 724 pregnant adolescents, 12% had been assaulted by the man who had impregnated them, and of those who had experienced relationship violence, 40% also reported experiencing violence by a family member or other relative.72

By age 15 years, most males and females have some dating experience, and by age 18, 89% have had dates. Adolescents are more likely to endorse stereotyped gender roles (dominant/aggressive males and submissive/supportive females) and are more likely to interpret jealousy, violence, or controlling behaviors as signs of love or devotion.73–75 Adolescents are also less likely to disclose abuse to parents from whom they are trying to individuate and separate and less likely to disclose abuse to peers for fear of being considered odd or rejected by the peer group.76 This stow of vulnerability, immaturity, and privacy places teens at risk for suffering that goes unsuspected and undetected. Homosexual teens have the additional anxiety of being “outed” should they disclose the abuse.77

Health professionals should routinely spend time alone with adolescents in the course of the history or physical examination in order to explore health issues such as reproductive and relationship health and prior exposures to violence, threats of violence, or bullying. The health professional should be familiar with the rights of minors regarding confidentiality, state laws regarding mandatory reporting of relationship violence, and sexual assault. Many states have enacted legal exemptions that allow minors as young as 12 years to seek a domestic violence protective order.

**ETIOLOGY**

**Intimate Partner Violence Social Ecology Model**

In order to prevent IPV or intervene effectively, one must understand its etiology. There are multiple theoretical explanations for why two people who shared some level of affection as dating, cohabitating, or married partners would become emotionally, physically, or sexually abusive relationships. These can perhaps best be organized using the Social Ecology Model that nests individual, family, community, and cultural factors (Fig. 65-2). IPV may arise with multiple factors from various levels or may arise due to one pervasive etiologic force.78

The “Individual” layer includes the biologic, ontogenic, or experiential make-up of a person. There appears to be an association between witnessing IPV in one’s family of origin and both IPV perpetration and victimization.79 Being a victim of child abuse also appears to increase the risk of IPV perpetration.78 There are certain personality psychopathologies that appear more often in IPV perpetrators, such as borderline, attachment, or antisocial personality disorders.80 A small number of studies have shown a relationship between mild traumatic brain injuries and increased anger and aggression, poor impulse control, and decreasing marital satisfaction.81

The second nested layer is the “Family” or the relationship itself with its own style of communication, decision making, and conflict resolution, also referred to as the “microsystem.” Male dominance and male control of financial decision making in a family have been predictors of societies that have high rates of violence against women.78 Not surprisingly, couples with high levels of conflict also have a greater risk of physical violence, and this risk increases when there is an asymmetrical power structure within the relationships.78

The third nested layer is “Community” or “exosystem” and refers to the neighborhood, institutions, local services, and social structures that surround the family. While IPV occurs across all socioeconomic strata, it appears to be more common in families with low income and in unemployed men.78 It is likely that income level is not the critical variable but the stress of poverty, crowding, or hopelessness that actually contributes to increased violence. Lack of social support for women and delinquent peer associations for men have both been associated with victimization and perpetration, respectively.78

Finally, the individual, family, and community all function within a society or culture with rules, laws, taboos, attitudes, and biases that is also referred to as the “macrosystem.” The predominant cultural theory is Feminist Theory, which states that violence against women results from gender inequity, both ideologic (belief, norms, values) and structural (access to and positions within social institutions).79 The more unequal women are to men, the more likely men are to be violent to women.80 This theory has found some validity when macro-level measures of women’s status across multiple countries were compared with the prevalence of violence against women.81 Dutton and Starzomski compared violent and nonviolent men on a measure to assess different forms of abuse and control. Although the use of male privilege did not appear to distinguish the two groups, violent men were more likely to employ emotional abuse or children as a way to control their partner’s action and also were more likely to minimize or deny the abuse.82

**Forms of Intimate Partner Violence**

It has been suggested that there may be two distinct forms of IPV: intimate terrorism and situational couple violence.83,84 Researchers Johnson and Leone (2005) essentially differentiated the two based upon the use of power to control and defined intimate terrorism as “the attempt to dominate one’s partner and to exert general control over the relationship” and situation couple violence as “violence that is not connected to a general pattern of control.”85 Johnson further described situation couple violence as usually less injurious and severe and more likely to be engaged in by either member of the couple.
Intimate terrorism was characterized as more injurious, more frequent, and almost exclusively perpetrated by men against women. Johnson further postulated that victims of intimate terrorism were more likely to be seen in clinic and ED settings; however, couple violence was thought to be more common overall.

Frye and Manganello in 2006 conducted an analysis to assess the prevalence of both intimate terrorism and couple violence as well as identify further characteristics of each. They concluded that there may not be a sharp demarcation between the two hypothetical forms of IPV and that IPV relationships might be defined along a continuum based on the level of control. The research team created a five-item index to measure controlling behavior: (1) partner tries to limit your contact with family or friends, (2) partner insists on knowing who you are with and where you are at all times, (3) partner becomes jealous and doesn’t want you to talk to other people, (4) partner prevents you from knowing about or having access to family income even if you ask, and (5) partner controls most or all of your daily activities (alpha = .72). They found evidence that controlling behaviors are present in 69% of physically violent relationships but present in only 11% of nonphysically abused controls. Their results further showed that primarily male characteristics differentiated the two forms of IPV. The ability to assess levels of control in relationships may have future utility in planning for appropriate safety and therapeutic interventions.

**CLINICAL FEATURES**

Patients who are currently experiencing or have previously experienced IPV may present to the ED for a wide range of health care issues. In several studies, women experiencing IPV generally reported their health to be poorer than those not exposed to IPV. IPV patients may present for care of an acute physical or sexual assault, or for the chronic sequelae related to a previous injury. They may present for treatment of an acute medical condition, or for the care of a chronic illness exacerbated by IPV. In addition, IPV patients present for mental health care, and with conditions related to alcohol and substance abuse. IPV patients’ presentations may be obvious, such as a geometrically patterned physical injury, or subtle, such as headaches due to repetitive blunt head trauma. Therefore, it is important that the HCP is aware of the broad possibility of IPV presentations as well as the comorbid conditions that are associated with IPV (Fig. 65-3).

**Medical History**

When HCPs are eliciting a history from a patient with injuries, they should always attempt to determine the mechanism of injury. If the patient reveals that the injuries are as a result of interpersonal violence, the identity of the other person as well as that person’s relationship to the patient should be ascertained, if possible, principally because the intervention for a victim who lives with the assailant will be very different from the intervention for a victim of an assault by a stranger. In order to make the patient feel more comfortable, the HCP may begin by asking whether the other individual was a stranger or an acquaintance. If the injury is due to IPV, the patient may be reluctant to divulge the information. Additional historical clues that an injury may be as a result of IPV are a changing history, a history that is inconsistent with the injuries, a statement by the patient that he or she is “accident prone,” and a past history of injuries.

Many IPV patients seek care for chronic conditions that are due to previous injuries or are comorbid conditions of the abuse. If the patient exhibits comorbid conditions of IPV, the HCP should consider the possibility of IPV. Likewise, if the patient has experienced IPV, he or she should be questioned about the presence of any comorbid condition (see Fig. 65-3). Other findings in the medical history that may be suggestive of IPV include a delay in seeking medical care or noncompliance with medications and/or medical appointments, and this may be due to the abuser’s controlling the patient’s access to care. Frequent visits to the ED and alcohol and substance abuse are also highly associated with IPV.

**Physical Examination**

IPV patients frequently present to the ED on account of acute injuries. When examining an injured patient, the HCP should look for clues that the injury may be an intentional injury. Signs of an intentional injury include a central location (e.g., trunk, breasts), bilateral injuries (both arms or both legs), defensive injuries (e.g., ecchymoses on the back of the hand because of protecting the face), and patterned injuries (having the markings of an object such as the sole of a shoe or a burn with the imprint of an iron). Common locations for IPV injuries are the head, face, and neck. Types of injuries may include facial contusions, lacerations and fractures, traumatic alopecia, concussion, skull fractures, and intracranial hemorrhages. Injuries of varying severities to the eyes, ears, mouth, and teeth also occur commonly. Extremity injuries with “grab” marks (fingertip contusions) to the upper arms are suggestive of IPV. Anogenital injuries should alert the HCP to the possibility of sexual assault. Abdominal trauma in pregnancy should also heighten the HCP’s concern about underlying IPV. If the injuries are incidental findings, the HCP should be prompted to ask additional questions about IPV. Injuries should be assessed for location, size, swelling, tenderness, coloration, evidence of healing, and any pattern present. In noting the color of each ecchymosis, the HCP should be careful not to make a determination as to the age of each one, as this may vary depending on the force, the vascularity of the tissue injured, the age and health status of the victim, and the presence of medications or use of alcohol that can alter coagulation profiles.

Other common medical presentations of IPV patients other than injuries include cardiorespiratory illnesses (palpitations, chest pain, asthma exacerbations, shortness of breath), gastrointestinal disorders (functional bowel disease), gynecologic conditions (chronic pelvic pain, dyspareunia, sexually transmitted infections, HIV, urinary tract infections), neurologic conditions (headaches, vertigo), as well as general constitu-
tional complaints (weakness, fatigue, dizziness, chronic pain). For this reason, the HCP should perform a thorough physical examination, including a neurologic examination, due to the possibility of repetitive blunt head trauma or anoxic brain injury due to strangulation from IPV.

**Mental Status Examination**

The HCP should assess any patient known or suspected of being exposed to IPV for mental health conditions associated with IPV. IPV victims frequently suffer from depression, suicidal ideation, homicidal ideation, post-traumatic stress disorder (PTSD), insomnia, eating disorders, and alcohol and substance abuse. In a meta-analysis of mental health disorders among women who had experienced IPV, the weighted mean prevalence was 50% for depression, 61% for PTSD, and 20.3% for suicidality. Higher prevalence rates were seen in women with more severe abuse or who were in shelters or court programs. These rates are all significantly higher than those of individuals who have not experienced IPV. IPV patients should also be questioned about alcohol and substance abuse, a common coping mechanism or form of pain control for IPV patients.

**Other Intimate Partner Violence Injuries**

Strangulation, mild traumatic brain injury, and intimate partner sexual abuse are three forms of injury that occur frequently in IPV but historically have been underrecognized by HCPs.

**Strangulation**

Strangulation is a type of asphyxia caused by the compression of the veins and arteries in the neck or the trachea. The compression can be applied using a body part of the perpetrator such as one or two hands, forearm, or knee, or a ligature such as a necklace or piece of clothing worn by the IPV victim. When asking patients if their partner attempted to strangle them, it is suggested that the lay term “choked” be used because more people associate strangulation with a rope or object and associate the word choking with compression by the hands. Patients may complain of a hoarse voice, pain or difficulty swallowing, neck pain, difficulty breathing, loss of consciousness, incontinence, or confusion, or they may have no symptoms. On examination they may have a hoarse or muffled voice, difficulty swallowing, neck tenderness, respiratory difficulties, stridor, laryngeal fracture, facial petechiae, subconjunctival hemorrhages, ecchymoses or ligature marks on the neck, or altered mental status. They may also have a normal examination that does not show any specific signs of strangulation. Direct laryngoscopy, computed tomography, or magnetic resonance imaging should be considered in any symptomatic patient in order to determine the extent of the injuries, and longer periods of observation are recommended as airway swelling can progress over time. The post-strangulation patient should be referred for early follow-up upon ED discharge.

**Mild Traumatic Brain Injury**

According to one study, 71% of women experiencing IPV have incurred traumatic brain injury (TBI) due to a physical assault and 51% had incurred multiple episodes of TBI from repetitive assaults. In another study, approximately three fourths of IPV victims had symptoms of TBI. Yet, TBI in IPV victims is underrecognized. Female IPV victims appear to be more at risk for postconcussive syndrome than men. Female IPV victims are also at risk for second impact syndrome, a form of TBI in which cerebral edema occurs due to repeated blunt head trauma days to weeks after an initial episode of TBI, but prior to the patient’s recovering from the initial injury. IPV patients may also sustain TBI due to “shaken adult syndrome,” resulting in diffuse axonal injury. They may present with retinal hemorrhages, subdural hematomas, and ecchymoses of the upper arms and chest, much like the shaken babies demonstrate. IPV patients frequently report difficulty concentrating, memory problems, headaches, depression and anxiety, and confusion, and problems with judgment, problem solving, and decision making. These IPV patients are often labeled as having borderline personalities, post-traumatic stress, or depression. The sequelae of TBI, which is frequently undiagnosed and under-recognized, include neurocognitive deficits and long-term disability. It has been postulated that perhaps TBI interferes more with a patient’s ability to make safer choices than has been previously recognized. The IPV patient with mild TBI should be referred to neurology for a comprehensive neurocognitive assessment.

**Intimate Partner Sexual Abuse**

Approximately 8 to 14% of women are sexually abused during their lifetimes by an intimate partner, with this number being even higher in clinical populations. While societal biases consider intimate partner sexual abuse as less severe and blame the victim more often than in stranger sexual assault, the sequelae of intimate partner sexual abuse are at least as serious as those of stranger sexual assault. In addition, victims of intimate partner sexual abuse were more likely to suffer from greater nongenital injuries than victims of stranger assault. When questioning IPV patients about intimate partner sexual abuse and rape, the HCP should ask the patients whether they have ever been forced by their partner to do sexual activities they did not want to do, rather than asking if they have been raped or sexually assaulted. Many IPV patients do not consider that they have been raped or sexually assaulted, if it was their partner, husband, or boyfriend who was the perpetrator. Many IPV patients also do not recognize that sexual activity under coercion or threat is a form of sexual assault.

**DIAGNOSTIC STRATEGIES**

The ability of a clinician to identify and diagnose IPV in the ED largely relies on the interaction between the clinician and patient, and the rapport the patient has with the clinician. In addition, because IPV is a shame-based health care problem, the more comfortable the environment and the clinician-patient interaction, the more likely the clinician will be able to have a conversation about IPV with a patient.

**Milieu Considerations**

Two important concerns of IPV patients related to disclosure of IPV are safety and privacy. While privacy and safety are issues for all patients, they are particularly critical for IPV patients, where the consequences of a breach of either could result in further injury or death. Specific provider behaviors that foster disclosure by IPV patients have also been identified. In addition, there are institutional barriers, professional and personal HCP barriers, and patient barriers that should be addressed and minimized in order to support the disclosure of IPV.
Privacy

One key behavior that promotes privacy is having a patient-only interview policy for at least part, if not all, of the interview, as patients who have experienced IPV may choose not to disclose their abusive relationship in the presence of their family, children, or friends, due to shame and embarrassment. Research has shown that women experiencing IPV prefer to talk to their physicians alone about the abuse. In the case where a partner is reluctant or refusing to leave, the HCP may need to be creative in finding an opportunity to talk to the patient alone, such as when a patient is in the radiology department. In addition, if an interpreter is needed, only hospital employees or a nationally based telephone interpreter service should be utilized. In smaller communities, prior to using a hospital employee to interpret, the patient should be asked if he or she knows or is related to the employee. If this is the case, a telephone interpreter service should be used, in order not to jeopardize the patient’s privacy. If a patient is asked to complete a written or computer-based questionnaire prior to being assessed by the HCP, he or she should be provided with a private, safe location in which to do this. Prior to questioning a patient about activities that must be reported to law enforcement, such as IPV in some states, the HCP should inform the patient about the limits of confidentiality. This is discussed further in the later section regarding Ethical Considerations.

Safety

The HCP needs to inquire of the patient as to the current location of the abusive partner as a first step to ensuring patient safety in the ED. An abusive partner may be in the waiting room, or may unexpectedly show up at the ED. In either case, the department should have a security protocol to protect patients when the threat level is high or if the batterer suddenly appears on the premises. Both IPV and sexual assault patients may feel that a room with a door is both protective of their safety and their confidentiality.

Provider Behaviors that Foster Disclosure

Numerous qualitative studies, primarily consisting of focus groups and surveys of women who are survivors of IPV, have been conducted to identify HCP behaviors that foster disclosure of IPV by patients. Women reported that they were more likely to disclose IPV to HCPs who listened attentively, conveyed compassion and concern, were nonjudgmental, and respected the woman’s right to autonomy in decision making. In addition, posters and patient brochures in the clinical setting made patients feel that the health care setting was a safe environment to discuss IPV with their HCP. Some women reported feeling more comfortable talking with a female HCP.

HCPs’ responses to surveys indicate that they are reluctant to ask patients about IPV for several reasons, including a lack of training about IPV, belief that there are no effective IPV interventions, time constraints, a perception that IPV patients are frustrating to deal with and do not follow the HCP’s advice, concerns about mandated reporting to law enforcement in some states, and a reluctance of potentially having to go to court. In addition, HCPs’ personal experiences with IPV, their biases about victims and batterers, and their belief that IPV is not a health care problem are all barriers that may limit an HCP’s ability to diagnose IPV in the ED.

Overcoming Barriers to Care

By finding ways to overcome barriers to the care of IPV patients, ED HCPs will be creating an environment that fosters disclosure and a feeling of safety for patients. Ways to overcome two institutional barriers to care of IPV patients, namely, safety and privacy concerns, have been discussed above. HCPs frequently state that they do not have time to spend assessing the IPV patient, given the complex nature of IPV. Having other trained personnel or a multidisciplinary response team to assist with assessment, referrals, and reporting can lessen this problem. In addition, partnering with a community advocacy organization that can provide crisis response and counseling benefits the HCPs and the patients. In addition, IPV patients who do not have injuries or positive responses to the Danger Assessment (Fig. 65-4) can be referred for further evaluation at a later time.

IPV patients are often embarrassed and ashamed about their situation, preventing them from feeling comfortable disclosing. By having patient awareness posters and information cards in the bathrooms, the message is made clear that patients can feel safe about talking about IPV with the HCPs. In addition, educating the HCPs not only helps them to understand the impact of IPV on the health of their patients, but will enable them to feel more comfortable talking about IPV with patients. The team approach is a very important one, as it provides good care for the IPV patients while providing support for all members of the ED.

Identification Through Disclosure and/or Pattern Recognition

Intimate partner violence is either disclosed to the HCP or is suspected by the HCP based on pattern recognition of signs and symptoms associated with IPV. The term disclosure means the act or process of revealing or uncovering. In relation to IPV, disclosure refers to the acknowledgment by a patient that she or he has experienced IPV. Disclosure may be spontaneous or prompted.

Spontaneous Disclosure

A patient may spontaneously disclose IPV either when being questioned about his or her chief complaint, or during the history of the presenting illness. While being triaged, a patient might state in response to a question as to why she came to the ED, “I was punched in the nose by my husband.” This is an example of spontaneous disclosure of IPV. Similarly, a patient being evaluated for decreased hearing might respond to a question about when the symptoms began, saying, “Ever since my partner slapped me across my ear.”

Prompted Disclosure

A prompted disclosure of IPV occurs when the patient reveals or affirms IPV when asked by the HCP. The HCP may ask about IPV in the process of routine inquiry (scan mode), such as in the social history, or may consider IPV in the differential diagnosis. Prompted disclosure may occur during the course of the medical history or physical examination when patterns in the history or physical examination arouse concerns (search mode). Pattern recognition is a cognitive process that clinicians use when diagnosing a condition. It involves sorting through findings from the history and physical examination, as well as the patient presentation, to arrive at a particular diagnosis, suggested by the clinical findings associated with that diagno-
Several risk factors have been associated with increased risk of homicides (murders) of women and men in violent relationships. We cannot predict what will happen in your case, but we would like you to be aware of the danger of homicide in situations of abuse and for you to see how many of the risk factors apply to your situation.

Using the calendar, please mark the approximate dates during the past year when you were abused by your partner or ex-partner. Write on that date how bad the incident was according to the following scale:

1. Slapping, pushing; no injuries and/or lasting pain
2. Punching, kicking; bruises, cuts, and/or continuing pain
3. “Beating up”; severe contusions, burns, broken bones
4. Threat to use weapon; head injury, internal injury, permanent injury
5. Use of weapon; wounds from weapon

(If any of the descriptions for the higher number apply, use the higher number.)

Mark Yes or No for each of the following. (“He” refers to your husband, partner, ex-husband, ex-partner, or whoever is currently physically hurting you.)

---

1. Has the physical violence increased in severity or frequency over the past year?
2. Does he own a gun?
3. Have you left him after living together during the past year?
   3a. (If have never lived with him, check here______)
4. Is he unemployed?
5. Has he ever used a weapon against you or threatened you with a lethal weapon?
   (If yes, was the weapon a gun? ______)
6. Does he threaten to kill you?
7. Has he avoided being arrested for domestic violence?
8. Do you have a child that is not his?
9. Has he ever forced you to have sex when you did not wish to do so?
10. Does he ever try to choke you?
12. Is he an alcoholic or problem drinker?
13. Does he control most or all of your daily activities? For instance: does he tell you who you can be friends with, when you can see your family, how much money you can use, or when you can take the car? (If he tries, but you do not let him, check here: ______)
14. Is he violently and constantly jealous of you? (For instance, does he say “If I can’t have you, no one can.”)
15. Have you ever been beaten by him while you were pregnant? (If you have never been pregnant by him, check here: ______)
16. Has he ever threatened or tried to commit suicide?
17. Does he threaten to harm your children?
18. Do you believe he is capable of killing you?
19. Does he follow or spy on you, leave threatening notes or messages on answering machine, destroy your property, or call you when you don’t want him to?
20. Have you ever threatened or tried to commit suicide?

---

Total “Yes” Answers

Thank you. Please talk to your nurse, advocate or counselor about what the Danger Assessment means in terms of your situation.

---

**Figure 65-4.** Danger Assessment instrument. (From Campbell JC: Danger Assessment. Available at [http://www.dangerassessment.org](http://www.dangerassessment.org). Copyright 2003. Permission to use this instrument in clinical settings has been universally granted by its creator. Dr. Campbell requests notification if the instrument is used in formal research studies.)

As discussed previously, there are signs and symptoms that suggest the diagnosis of physical, sexual, or psychological IPV. By questioning a patient who has a pattern of signs and symptoms suggestive of IPV about current or past abuse, prompted disclosure by the patient may reveal IPV.

**Routine Inquiry versus Screening for Intimate Partner Violence Identification**

Due to the high prevalence rates of IPV in health care settings and the varied presentations of patients to the health care setting, numerous professional medical organizations, regulatory bodies, as well as advocacy organizations have recommended routine “screening” of patients to identify those who are experiencing IPV. These organizations include the American Medical Association, the American College of Emergency Physicians, the American College of Obstetricians and Gynecologists, and the American Academy of Family Practice. However, the American College of Emergency Physicians has recently revised its policy to recommend that emergency HCPs assess patients for IPV. In the National Consensus Guidelines on Identifying and Responding to Domestic Violence Victimization in Health Care Settings, the Family Violence Prevention Fund, a national advocacy organization, also recommends routine “screening” in the health care setting. The term screening has been used in the IPV
literature to refer to a process of asking about past or current exposure to violent or abusive behavior at some point in the clinical interaction with every patient.

However, screening is actually a public health term with a very specific meaning and refers to the use of a specific test, examination, or procedure to identify an unrecognized condition or illness in an asymptomatic person. Early identification through screening enables early referral to effective interventions, resulting in decreased morbidity and mortality. The screening tests are validated, and the diagnosis is verified with a gold standard confirmatory test, such as a biopsy.

In 2004, the third United States Preventive Services Task Force (USPSTF) reported on their evaluation of the evidence regarding screening for family violence and IPV in the health care setting. In their report they stated that there was insufficient evidence for or against routine screening for IPV. These findings were largely due to a paucity of evidence in this field. They were also due to the evaluation of the available evidence relative to traditional screening methodology, which entails a burden to prove the effectiveness of the test questionnaire to decrease the morbidity and mortality due to IPV. In addition, the task force noted the lack of research to determine whether the routine inquiry is verbal, written, or computer-based. It was also noted that there was insufficient evidence relative to traditional screening methodology, which entails a burden to prove the effectiveness of the test questionnaire to decrease the morbidity and mortality due to IPV.

In addition, the task force noted the lack of research to determine whether screening for IPV did more harm than good. This is an area that requires further study to determine whether potential harms are actual or not. In a recent study, Houry did not find any adverse effects from questioning patients about IPV. It is important when interpreting the USPSTF report to realize that there was no evidence that providers should not ask patients about IPV. Exposure to ongoing IPV is likely to result in continued physical and sexual violence and psychological abuse.

When HCPs ask patients about IPV, they are identifying patients along the entire spectrum of IPV—those who have not been exposed to IPV and are not at risk for IPV, those who have not experienced IPV but are at risk for IPV, those who have experienced IPV but do not yet have health-related sequelae, and those who have experienced IPV and are very symptomatic with severe adverse physical and mental health sequelae due to the violence. Most patients who are experiencing IPV are fully aware of the violence and abuse, even if they choose not to disclose the violence to their HCP or the IPV goes unrecognized by the HCP. Further, there is no gold standard test against which to verify patient responses. While several questionnaires have been validated for use in identifying IPV, most have only been validated for use with female patients, and with select populations and clinical situations. Further, HCPs will only be able to identify IPV using a questionnaire if the patient chooses to disclose IPV at that particular time. So while the goal of being able to screen for IPV is a worthy one, the clinical reality is that we are carrying out a diagnostic assessment or routine inquiry.

**Assessment for Intimate Partner Violence**

The opinion of experts in the field, supported by practice-based evidence, is that HCPs should assess patients for IPV due to the adverse physical and mental health effects of IPV, the morbidity and mortality of IPV, the economic cost, and the effect on children. In addition, failure to ask about IPV may lead to misdiagnosis, inappropriate workups, excessive costs, and increased morbidity and mortality. Due to the varied presentations of IPV in the clinical setting, routine inquiry is recommended. In addition, several studies questioning women and IPV patients have found that they also support routine inquiry for IPV by HCPs. Routine inquiry may also be preventive; it may increase the patient's awareness of the impact of IPV on health, decrease the violence if referrals and interventions are provided, and lessen the impact of sequelae due to violence.

Prior to the HCP asking patients about IPV, the HCP should ensure that the patient is in as private an environment as possible, without family or friends nearby. Patients should be questioned in their primary language, using an interpreter service or hospital employee if needed. It is important that patients are informed if the HCP is legally required to report to law enforcement should the IPV patient disclose physical abuse. Routine inquiry about IPV may be conducted using a person-to-person interview or written or computerized questionnaires. The inquiry may consist of a few questions about IPV, or may be part of a larger health risk assessment, which is usually a written or computerized questionnaire completed by the patient prior to being evaluated by the HCP. There are advantages and disadvantages to each of these methods of inquiry. Some patients prefer responding to a written or computerized questionnaire. However, others may have literacy difficulties or may be intimidated by a computer. When conducting a person-to-person interview, framing statements can be helpful. These statements help to normalize the questions about IPV and make them seem routine and not prejudicial (e.g., “Because of the impact of violence on women’s health, I ask all my female patients these questions”). The HCP should use inclusive terms, such as partner or boyfriend. In addition, the HCP should make use of both direct and indirect questions (e.g., “Were you hit or hurt?,” “Is there anything else you would like to tell me?”). Rhodes found that when the HCP asked at least one additional related question, patients were more likely to disclose abuse. Brief instruments for use in asking about IPV are preferred by some HCPs, as they find standard questions easier to ask and remember. The Abuse Assessment Screen (AAS) and Partner Violence Screen (PVS) are both brief instruments for clinical use. The AAS has been validated in a variety of clinical settings, multiethnic populations, and in Spanish. The PVS was developed and validated in the ED.

An extensive list of IPV assessment tools is provided in compendiums published by the CDC. Ultimately, whether the routine inquiry is verbal, written, or computerized, the HCP will need to have an individualized conversation with the IPV patient, being sensitive to the presenting medical problems, race/ethnicity, language barriers, cultural

---

**BOX 65-1** **ABUSE ASSESSMENT SCREEN**

- Have you ever been emotionally or physically abused by your partner or someone important to you?
- Within the last year, have you been hit, slapped, kicked, or otherwise physically hurt by someone? If yes, by whom?
- Within the last year has anyone forced you to have sexual activities? If yes, by whom?
- Are you afraid of your partner or anyone mentioned above?

**BOX 65-2** **PARTNER VIOLENCE SCREEN**

- Have you been hit, kicked, punched or otherwise hurt by someone within the past year? If yes, by whom?
- Do you feel safe in your current relationship?
- Is there a partner from a previous relationship who is making you feel unsafe now?
beliefs, gender, and sexual orientation. A successful encounter with an IPV patient or a suspected IPV patient is one in which the patient is treated with compassion, feels safe, and is provided with information, resources, and referrals regardless of whether he or she disclosed IPV or not.

** MANAGEMENT **

While patients may disclose IPV, they may be unwilling to pursue any suggestions for addressing the IPV. The reasons are myriad, but generally, the first and foremost factor is fear. Victims may fear for their own safety, fear for the well-being of their children, fear because they lack any means for economic independence, fear they will be deported if their spouse is arrested for a crime, fear they will be abandoned by family, friends, church, or community, and fear that the unknown could be worse than the known risks they are willing to endure. The cost of disclosure or the cost of making change may simply exceed the known benefits. Patients may negotiate their options or reject any options presented to them. Patients sometimes make choices that physicians believe may increase their risk for a poorer outcome, but the physician’s role is to provide recommendations for care, fully discuss the potential benefits and risks, document the discussion, and verify the patient’s capacity for noncoerced decision making. While a patient may not make the decisions the provider would prefer, a respectful interaction that leaves the door open for reconsideration or a return visit may be more powerful than appreciated at first glance. Revictimizing an IPV patient through abusive use of professional power or disparaging remarks may be more harmful than realized.

Emergency departments need to plan for IPV patients as their care is multifaceted, often requiring social services, law enforcement, mental health services, and occasionally child welfare services. The preplanning for a routine response or a crisis response should the threat of violence escalate is not only important for patient care, but also may increase the willingness of health care staff to address IPV in their patients. Hospital policy may need to allow for short-term admissions to provide for a safe haven in the rare case that emergency shelter services are not available and the patient has no other recourse.

** Initial Intervention Assessment **

Once IPV is identified, the patient should undergo a brief assessment by any member of the IPV response team that answers the following questions:

- What are the nature, scope, and consequences of the abuse in terms of its impact on physical and mental health?
- What is the level of danger and risk of a lethal outcome?
- What strategies have been tried and what are possible sources of support or major barriers that need to be addressed today in order to assist patient safety?
- If there are children, is the parent becoming concerned for the children’s safety and well-being?
- How does the patient view his or her current situation and desire for change?

The assessment then directs the intervention (Table 65-1).

</table>
Of these, assessing for the risk of a lethal outcome has been the most extensively researched. Women are killed by current or former intimate partners almost nine times more often than by a stranger.\textsuperscript{123} Contrary to the reporting by the lay press, IPV fatalities don’t usually occur as a freak event in an otherwise happy family. IPV is a precursor to the homicide in 65 to 75% of cases.\textsuperscript{124–126} Of even greater concern for health professionals is that 43 to 47% of IPV homicide victims saw an HCP within a year prior to their death.\textsuperscript{12,13} IPV homicide is the seventh leading cause of premature death for women and is the second leading cause of death for African American women 15 to 34 years of age.\textsuperscript{122} The incidence of fatal IPV due to homicide has continuously decreased since the mid-1970s, and this is attributed to societal shifts to more openly address family violence and to improvements in criminal justice, social service, and health system responses to both victims and perpetrators.

Twenty risk factors have been validated as highly associated with an IPV homicide. Campbell and colleagues—in a multicity, retrospective, case-controlled study using police files, surrogate interviews, and survivor interviews—compared case histories of fatal and nearly fatal cases with women who had been physically abused but without a life-threatening assault. Variables that significantly differentiated fatal and nearly fatal cases from controls became the elements of the Danger Assessment.\textsuperscript{124} Some of these elements include stalking and harassment of the victim, estrangement (physical or legal separation), perpetrator access to a gun or prior threats with a gun, history of forced sex, and physical abuse during pregnancy. This is a two-part assessment that begins with a severity ranking that stimulates recall, and the second part consists of 20 dichotomous items that are validated risk factors for IPV homicide (see Fig. 65-4). A brief online training program (www.danger-assessment.org) provides instructions for weighted scoring, and then the copyrighted tool can be used for free. However, even without the weighted scoring, more affirmative responses indicate a greater risk of a fatal outcome. Assessing risk factors for a possible fatal outcome is good medical care and may be protective. Fifty-four percent of women killed and 45% of attempted homicide victims did not accurately perceive their risk of being killed by their partner.\textsuperscript{124} In all likelihood, health and criminal justice professionals have also previously underestimated the risk of a fatal outcome when caring for IPV victims.

**Clinical Intervention for Intimate Partner Violence Victims**

Clinical intervention for IPV in the ED is just like intervention for any other potentially life-threatening disease. System readiness coupled with practitioner skill is believed to lead to improved outcomes.

**System Readiness**

System readiness should address procedures to promote patient privacy and safety within a multidisciplinary team approach. On the rare occasion of a battered victim who remains in danger, a “code black and blue” would require the response of appropriate medical and surgical personnel, social services, IPV experts, site security, and community law enforcement. At a bare minimum, system readiness in the ED refers to ongoing professional education, established quality improvement measures to monitor quality of care, protocols for intervention, patient education, and established means for safe follow-up.

Emergency departments can take advantage of a tool developed by the Agency for Healthcare Research and Quality (AHRQ) to assess if processes are in place to respond to IPV (www.ahrq.gov/research/domesticviol/).\textsuperscript{127,128} The tool addresses (1) hospital policies and procedures, (2) the physical environment, (3) the cultural environment, (4) provider education, (5) screening and safety assessment, (6) documentation, (7) intervention services, (8) evaluation and quality improvement measures, and (9) collaborative agreements. Inter-rater reliability was very high (Kronbach’s alpha ranging from 0.97 to 0.99 in the experienced coders and 0.96 to 0.99 in the inexperienced coders). The instrument can be used for assessment and to set benchmarks for quality improvement. Instructions for use and scoring are available from AHRQ.

Three models of system intervention have been identified and they may be blended in various ways: Advocacy Partnering, Forensic Medicine, and a Specialty Care Model. The Advocacy Partnering Model is based on negotiated agreements between health clinics or hospitals and community IPV service providers. Trained peer counselors respond to provide bedside or telephone consultation, speaking directly with patients and providers to conduct a needs assessment and plan for initial intervention, or in some places, for ongoing case management and more chronic care. The Forensic Medicine Model also incorporates advocacy partnerships and provides, in the case of physically or sexually abused victims, nurses or physicians who have received advanced training in the retrieval, documentation, and storage of physical evidence, forensic photography, presentation of evidence in the courtroom, and expert interpretation of findings. In Specialty Care Models, patients can be referred to clinical experts or centers that specialize in trauma recovery. In pediatrics, child abuse is now a recognized subspecialty given the scope of both knowledge and skills the care of abused children requires. Some departments (e.g., behavioral health) or individuals have established IPV care as an area of expertise, and once the patient is medically stabilized, referral for bedside or delayed consultation is made just as for any other ED problem.

**Health Care Provider Intervention**

Intimate partner violence is a socially stigmatized issue and, as such, requires concerted effort on the part of the clinician to establish trust and convey empathy. An empathic and nonjudgmental assessment and respectful discussion of options with a trusted HCP are postulated to have potential therapeutic benefit in and of themselves. The assessment guides decision-making regarding the needs for immediate or delayed intervention. In addition, the emergency HCP might consider a brief intervention for substance abuse and brief interventions to ameliorate PTSD. The ED HCP will encounter five levels of patients, based on IPV exposure and risk. Each level requires varying intervention strategies and critical elements for documentation (Table 65-2).

Safety planning is a harm reduction intervention in that the patient may be returning to a dangerous situation but certain behavior changes may contribute to a less negative outcome. Needle exchange programs are examples of a harm reduction effort to prevent additional illness in intravenous drug users. Emergency preparedness for disaster events is another example of a harm reduction intervention. IPV patients may be discharged to a situation with risk of continued violence. Strategies for avoiding further harm may be both protective and empowering. Planning for safety during violent outbursts (getting to a room with a lockable door and exterior window) or for immediate escape (placing a suitcase in the safekeeping of a trusted other with clothes, documents, and extra cash) are examples that can be developed with the patient.\textsuperscript{129}
In the past 20 years, community agencies or victim advocacy organizations have been developed in every state to provide services for IPV victims and their children. The federal Violence Against Women Act provides considerable funding to support these service providers. While most of the time patients are referred to such agencies for follow-up, more and more agencies now respond to health care requests for bedside or telephone consultation. Information about what agencies are available in a specific community is easily available through the National Domestic Violence Hotline at 1-800-799-SAFE or (TTY) 1-800-787-3224. Sullivan examined the effect of community-based advocacy services after a shelter stay and found that at 2-year follow-up, IPV victims who had received the advocacy intervention experienced less physical abuse, increased quality of life, and accessed more community IPV resources compared with the control group. Of note, 25% of the intervention group, compared with 10% of the control group, had experienced no further violence following the intervention.130

Bedside consultation was started in EDs in Kansas City, Missouri, and analysis showed that patients who received bedside counseling with a victim advocate were more likely than those who had social service consultation alone to call the police for a subsequent event (18% vs. 39%, 95% confidence interval [CI] difference 1–40%), seek emergency shelter (11% vs. 28%, 95% CI difference 6–27%), or obtain counseling (1% vs. 15%, 95% CI difference 7–21%) than controls.131 In a study by McFarlane, telephone follow-up calls for harm reduction counseling resulted in the increased adoption of safety behaviors that remained even 2 years after counseling ended.132 However, further research is needed. Canadian researchers examined 22 published reports involving IPV interventions to which a primary care clinician could refer a patient. Each study examined 22 published reports involving IPV interventions to which a primary care clinician could refer a patient. Each study

### Interventions and Referrals for Perpetrators

Interventions for IPV perpetrators have not been shown to be as effective as hoped.138-141 The problem is that a “one-size-fits-all” approach appears to be inadequate for the known typologies of violent offenders. The current treatment modalities are organized according to etiologic theories142: (1) cognitive-behavioral treatment focuses on deficient thought patterns such as rigid beliefs and limited problem solving; (2) psychodynamic treatment addresses unresolved physical and emotional trauma; and (3) feminist models focus on educational efforts to increase awareness of oppressive, sexist attitudes and foster nonoppressive, egalitarian behaviors. Conjoint treatment for couples remains controversial, and the primary objections center around safety concerns for victims. In the primary care setting, researchers found that 13% of men who participated in the study disclosed IPV perpetration.143 Right now, patients who disclose histories of interpersonal violence, with partners, acquaintances, or strangers, should all be referred to social services for further evaluation and appropriate referral. Once arrested, the criminal justice system does not generally conduct comprehensive assessments, so offenders do not have as many treatment options. Unfortunately, that usually means that recidivism for offenders is quite high.
Cultural Issues

The phrase cultural competency has been previously misinterpreted to mean knowledge of another culture. While knowledge is valuable, the ability to be open and learn about other cultures and moving beyond the restrictive perspective of one’s own culture manifests competency and has also been termed “cultural humility.” In regards to IPV, beyond assessing for possible strengths or barriers within a given culture for an IPV patient, a few special considerations are worth mentioning:

- Language interpreters should be professionals and nonfamily members, with some training and background in the dynamics of IPV. There are some languages that do not readily translate the phrases or the concepts for family violence.
- Immigrant victims fear deportation for themselves should they disclose IPV and, in most cases, fear deportation for their partners. There are protections within the federal Violence Against Women Act that allow victims to remain in this country even if their legal spouse and/or sponsor is deported.
- Some victims of color may be reluctant to contact law enforcement due to apprehension regarding racism. While the desire to be safe and free from violence is real, the fear of brutal or unfair treatment for their partner is also real.

While not a distinct cultural group, health professionals should appreciate the barriers faced by IPV patients from rural areas (fewer resources, less privacy), the disabled (few shelter programs with full access, need and expense for sign language interpreters), and gay and lesbian IPV victims (few shelter services for gay men, “outing” or disclosing a person’s gender orientation as a coercive threat). Socioeconomic status may also be a barrier for intervention. The lack of independent financial resources or educational/vocational training limits options for change at all socioeconomic levels.

Interface with the Criminal Justice System

Intimate partner violence impacts patient health both acutely and with exposure over time and is considered to be a public safety issue. As such, domestic violence is a crime in all 50 states, as is spousal rape. A criminal justice response can be helpful. Mandatory arrest policies provide a “cooling off” period that provides time for patients to implement safety plans or safer shelter. Orders of protection may be useful in helping victims to feel safer, although at least one study among African Americans reported heightened fear of retaliation when protective orders were obtained. Protective orders can be written such that they allow for immediate search and seizure of firearms, and protective orders link into databases that restrict firearm purchase by the perpetrator. Finally, victims of crime restitution programs can assist patients to buy and install home security systems, change residences, or pay for uncompensated medical or mental health care for victims and/or their children.

In most states, HCPs negotiate with patients to determine how and when to contact law enforcement. In some states, health care professionals are required by law to report any patients who have sustained injury with a weapon, and a few states require reports to law enforcement, regardless of patient consent for any patient who has injuries that appear to be intentionally inflicted. The most restrictive reporting mandates have been implemented because the IPV victim is perceived as a “vulnerable person” just as in child and elder abuse, and proponents advocate that victims be assisted with the full resources of the health and safety system. Unfortunately, there is neither sufficient evidence for nor sufficient evidence against mandatory reporting laws by health professionals to law enforcement in the case of IPV. There are survey data that reveal physician anxiety about proceeding without patient consent, and there are mixed results from victims themselves, some seeing the law as helpful and other seeing it as potentially harmful.

Ethical Considerations

Certain ethical issues will need to be addressed in designing ED intervention protocols.

Confidentiality

Despite all the increase in public awareness, IPV as a shame-based disease and bias, both professional and institutional, still remains. Breaches of confidentiality could put the victim at heightened risk. Some of the questions to be addressed in this regard are:

- What if the principal insured party is the abusive partner? What procedures are in place between the provider and the third party insurer to protect the confidentiality and safety of IPV victims?
- Are there any routine follow-up processes in place, such as patient satisfaction surveys, that might inadvertently contact a patient and alert the abusive partner to a health care visit?
- What if a minor discloses IPV occurring in the home and the abusive parent seeks access to the medical record?
- If IPV is noted on the medical record, could this be grounds by health or home insurance companies to cancel insurance?
- What if the patient discloses IPV as the cause of injuries and now the provider, by law, must notify law enforcement of possible criminal behavior?

All of these have been addressed in various ways, some at the institutional level, some through collaborative agreements, and some through state legislation. Regardless, the potential for breach of confidentiality must be recognized, and limits to confidentiality, including any reporting mandates, should be communicated to patients during ED registration or as soon as possible.

There are some protections for IPV patients within the Health Information and Portability and Accountability Act (HIPAA). Under HIPAA, physicians may not generally share confidential health information without the written approval of patients unless mandated by state law. However, physicians may disclose protected health information to government authorities or social services in the case where abusive behavior has been suspected to have occurred. Likewise, unless mandated by law, a physician has discretion to withhold information when he or she believes the notification will place the patient at “serious risk of harm.” HIPAA also allows patients to specifically request nonrelease of protected health information to specific persons or agencies, and patients can request that they be notified of any release that does occur. IPV patients can request their names be withheld from any registry system when hospitalized, or hospitals can routinely admit IPV patients as a “Jane Doe” to ensure both safety and confidentiality. These are HIPAA protections that an IPV response team should know and routinely discuss and facilitate with IPV patients.
If a patient discloses violent or abusive behavior, the physician operates under obligation of confidentiality and cannot disclose to police unless required by law. The duty of a citizen to report criminal behavior is a communal value and appears to clash with the duty to maintain patient confidence. However, this duty to confidentiality is also a communal value, and unless over-ridden by legal mandates, the HCP cannot report criminal behavior but can warn intended victims if there is a threat to their safety.¹⁴⁴

Informed Consent and Autonomy

Reporting, when required by law, is permissible by HIPAA and does not require patient consent, although addressing any concerns to safeguard the patient is an obligation of the health provider or the institution that receives the report. For example, California mandates physicians and surgeons to report patients with injuries suspected to be assault related to law enforcement. However, the reporting physician can request immediate bedside response rather than a delayed home response, and the report can indicate safe strategies for contact that the patient has identified.

IPV patients are not always free to act of their own will in health care decision-making. Coercive decision-making is not autonomous decision-making. Fear may be so profound that decision-making is impaired, thus jeopardizing informed consent. In a Montana malpractice suit, the ED physician and hospital were sued for failure to accurately diagnose and failure to provide for patient safety when an IPV patient was discharged to home only to suffer devastating physical injury by her abusive partner.¹⁴⁵ According to the plaintiff’s attorney, the ED physician testified in deposition that IPV was discussed and safety issues addressed; however, the patient testified that she was at the hospital under coercion of her boyfriend, who had made specific violent threats to her should the IPV be disclosed (personal communication with C. Mitchell). While this case was settled prior to court judgment, the coercive nature of extreme fear and its impact on informed consent and clinical decision-making are challenges for both clinicians and ethicists alike.

¹Tarasoff v. Regents of University of California (1976) 17 Cal. 3d 425.

### Documentation

#### Medical Record

The ED physician cares for victims of violence and abuse on a daily basis. Because violence and abuse are both health and criminal justice problems, there is increased likelihood that the medical record may be introduced or referred to in criminal or civil proceedings. In addition, many states have evidence rules that allow the introduction of prior evidence of physical abuse (e.g., the medical record) to demonstrate a pattern of behavior even if the actual criminal charges or civil litigation is pursued many years later.

In IPV cases there are key elements in the history of the presenting illness, physical examination, and discharge instructions that should be addressed and documented (Table 65-3).

#### Diagnostic Coding

*Intimate partner violence* is the preferred term for health surveillance and research as defined by the CDC. *Domestic violence* is commonly used by the general public to refer to IPV but is specifically used by criminal justice to refer to physical abuse by a current or former intimate partner. **Adult Maltreatment** is the coding term used in the International Classification of Diseases (ICD) (995.8__). The last digit varies for different types of adult maltreatment: physical abuse (995.81); emotional/psychological abuse (995.82); sexual abuse (995.83); neglect (995.84); and other abuse or multiple forms of abuse (995.85).

In the 10th version of the ICD, a prefix can be given for Adult Maltreatment to designate suspected (T4) or confirmed (T7) IPV. The reason for this is that practitioners have been hesitant to document suspicions of abuse due to the desire to protect patient confidentiality and safety; however, failure to document adult maltreatment has impeded both continuity of care and surveillance. In the past, victims often received a psychological diagnosis that not only failed to recognize the primary etiology but also failed to recognize the relational aspect of IPV and appeared to be victim blaming, further stigmatizing patients.

Documenting suspicions of abusive behavior in the differential diagnosis is important because confirmation of shame-based health issues may take time and repeat discussions are not usually within the purview of the ED physician. In addi-
Forensic Documentation

The medical record becomes a forensic record when it becomes part of a legal process. The word forensic means “pertaining to the law.” However, a medical record does not need the degree of detail or scope in the history or physical examination that a formal forensic examination does. Sexual assault and child abuse patients have, for many years, benefited from the additional service and care of medical forensic teams that can coordinate with law enforcement and then follow meticulous protocols to collect and document detailed findings. Other members of the team can provide interventions for medical and mental health needs and establish care for longer term needs. These programs have served as models for IPV forensic care. California has developed clinical guidelines, a forensic protocol, and a form for the forensic medical examination of victims, which is available online (www.oes.ca.gov/WebPage/oeswebsite.nsf/Content/5B3A31407BB2C92D882574BF005A603E?OpenDocument). Multiple law enforcement agencies now contract with forensic medical personnel to conduct the forensic examination, collect physical evidence, and present courtroom testimony. Of note, forensic examinations are only done with the full consent of patients, which differs from some state laws regarding reporting. Forensic examinations are usually time consuming and detailed, while reporting seeks to capture critical elements for either public health surveillance or to alert public safety departments of a possible violent crime.

Participation in Public Health Intimate Partner Violence Activities

Emergency department HCPs play a critical role in surveillance of IPV both through accurate diagnosis and documentation of patients who have suffered IPV. In addition, ED physicians serve as valuable members of fatality review teams that examine the events leading up to a domestic violence fatality and attempt to identify either missed opportunity for prevention or strategies for an improved response to family violence. Given the multidisciplinary nature of IPV, community coordinating councils examine components of the system response components and work to improve interagency relationships. Other opportunities to improve health policy exist within organizations such as the Injury Control Committee with the American College of Emergency Physicians, the American Medical Association’s National Advisory Council on Violence and Abuse, the Family Violence Prevention Forum within the American Public Health Association, and many others.

KEY CONCEPTS

- IPV is pervasive and difficult to diagnose. It can impact children, adolescents, adults, and elders. The ED HCP will care for both victims and perpetrators.
- Identification of IPV is through a process of patient disclosure and pattern recognition by the HCP. Just as with other medical problems, accurate diagnosis relies on interview, physical examination skills, and pattern recognition.
- Comorbid conditions. Some conditions are highly associated with IPV, and when identified should prompt the HCP to consider IPV. When a patient discloses IPV, the HCP, in turn, should assess for comorbid conditions.
- Readiness to intervene. A coordinated multidisciplinary team response using existing services (e.g., community advocacy agencies, forensic teams) will facilitate patient access to multiple resources that are often needed to promote the safety of victims and children. Having a response system in place will be time saving for the ED HCP.
- Documentation. After identifying or diagnosing IPV, the HCP should document the diagnosis Adult Maltreatment on the medical record. Further, all interventions, referrals, and mandatory reports should be documented. In addition to the medical record, the patient may have a forensic record in which evidence is documented for the purposes of legal proceedings.
- Patient disclosure of IPV is not necessary for a successful encounter with a patient. The goal of the HCP should be to provide a caring, compassionate environment in which the patient feels safe to talk about IPV now or in the future. All patients, whether they disclose IPV or the HCP suspects they are experiencing IPV, should be provided with written information and appropriate resources for IPV.

Elder Abuse and Neglect

Deirdre Anglin and Diana C. Schneider

PERSPECTIVE

Background
Currently, 12.4% of the population in the United States is estimated to be 65 years of age or older. The elderly segment of the population is expected to increase to 16.3% of the population by 2020 and 20.7% of the population by 2050. Further, the “oldest” old (85 years of age and older) will make up an increasing proportion of the population. At this time, older patients comprise about 15% of emergency department visits. This number is expected to increase to 25% by the year 2030, with 5% being over 85 years of age.

With advanced age, vulnerabilities increase, such as significant physical and cognitive decline, expended financial resources, and uncertain medical insurance. As the U.S. population ages, maltreatment of elders is increasingly identified. Further, the World Health Organization has recognized that abuse and neglect of elders are global health problems.

The first reports of “granny battering” appeared in the medical literature in 1975. In 1978 the U.S. House of Representatives Select Committee on Aging held hearings on elder abuse. This committee concluded that elder abuse was a nationwide problem that suffered from severe underreporting. The committee recommended that the federal government assist states to develop agencies responsible for collecting reports and identifying and managing cases of elder abuse. In 1981 the Prevention, Identification and Treatment of Elder Abuse Act was introduced into Congress to standardize definitions of elder abuse. In spite of being introduced numerous times, it was never passed. In 1990, the House Select Committee met to determine what progress had been made in the problems related to elder abuse. They concluded that elder abuse was increasing and that it continued to remain woefully underreported, even though 80% of states had statutes mandating reporting of elder abuse. Further, the committee noted that the federal government had not passed legislation to provide assistance to the states to deal effectively with the national problem of elder abuse. In 1991, the National Institute on Elder Abuse was established to focus increased attention on the issue of elder abuse. An amendment to the Older Americans Act in 1992 established a national elder abuse policy and provided some funding to states. In the same year, the Joint Commission on Accreditation of Healthcare Organizations set standards for emergency departments that included having criteria for the detection and management of elder abuse among patients.

Elderly individuals may be isolated from society as a result of physical illness, disability, mental illness (e.g., dementia), and age. Visits to physicians by elderly persons may provide their only contact outside the family. Elderly persons frequently present to the emergency department for medical care. Therefore, emergency physicians have the opportunity to diagnose suspected elder abuse and initiate further evaluation by elder abuse teams and Adult Protective Services. However, one survey suggests that emergency physicians may lack awareness and adequate training about elder abuse. In this survey, 79% of emergency physicians reported they had treated a case of elder abuse in the previous year, but only 50% said they had reported the abuse. Of respondents, 28% believe elder abuse is rare and 84% rarely ask their patients directly about elder abuse. Only 31% of emergency physicians responded that they are aware of a written protocol for elder abuse in the emergency departments where they practice, and just 38% said they are familiar with their state laws pertaining to elder abuse. In addition, only 40% responded that they are aware of types of community services available for victims of elder abuse, and only 25% could recall education during their residencies about elder abuse. Hopefully, through education and increased awareness, these numbers will rise.

Epidemiology
It has been estimated that 2 million elders are neglected or abused annually in the United States. In a survey of Adult Protective Services throughout the United States, between 2000 and 2004 there was a 19.7% increase in reports of elder abuse and a 15.6% increase in substantiated cases of elder abuse. According to the National Elder Abuse Incidence Study, the median age of victims of elder abuse is 77.9 years, and two thirds of victims are women. Of the identified elder abuse victims, 66% are white, 19% black, and 10% Hispanic. More than two thirds of perpetrators of elder abuse are family members, primarily spouses and grown children, and the overwhelming majority of victims live with the perpetrators. A total of 77% of victims are able to care for themselves; 60% of victims are either very confused or occasionally confused. In addition, 37% of elder abuse victims are moderately depressed and 6% are severely depressed. Surveys of noninstitutionalized elderly people in the community have revealed that between 3 and 5% had...
experienced elder abuse or neglect, and the rates of psychological abuse were even higher.15 Numerous studies have shown that as few as 1 in 14 cases of elder abuse is actually reported.

■ DEFINITIONS AND TYPES OF ELDER ABUSE

Some of the difficulty in establishing the true incidence and prevalence of elder abuse stems from the lack of uniformity of definitions of elder abuse, both among researchers and in legislation. Definitions vary from state to state and often lack objective criteria for reliably establishing a medical diagnosis. Elder abuse is a form of family violence, along with child abuse and intimate partner violence. There are three main categories of elder abuse: domestic elder abuse, institutional elder abuse, and self-neglect or self-abuse. Domestic elder abuse includes any form of elder abuse that occurs in the elder’s home or the caregiver’s home by a family member or the caregiver. Institutional abuse includes any form of elder abuse that occurs in a residential facility for elderly persons, usually by individuals who are hired to provide care. Self-neglect or self-abuse is the result of the behavior of an elderly person and threatens the well-being of that individual. Self-neglect usually involves the refusal or failure of elderly individuals to provide themselves with basic necessities, such as food, water, shelter, medications if indicated, and appropriate personal hygiene. In 45% of cases of self-neglect, elders 80 years of age or older are involved.16 Self-neglect does not include mentally competent elderly individuals who understand the consequences of their decisions.

In addition to the three main categories of elder abuse, 33 forms of elder abuse have been described.17 These forms of elder abuse can be grouped into six types: physical abuse, sexual abuse, emotional or psychological abuse, neglect, abandonment, and financial or material exploitation.18 In a study of substantiated cases of elder abuse, 58% involved neglect, 11% physical abuse, 15% exploitation, 15% emotional abuse, and 1% sexual abuse.13 Victims of elder abuse are often subjected to multiple types of elder abuse.

Physical abuse is defined as the intentional use of physical force that may result in bodily injury, physical pain, or impairment.16 Physical abuse is the most readily detected type of elder abuse. It includes slapping, hitting, kicking, pushing, pulling hair, and burning. Physical abuse may include overmedication or undermedication, the use of physical restraints, or force-feeding. It may also involve the use of household objects as weapons, as well as the use of firearms and knives.

Sexual abuse is defined as any type of sexual contact with an elderly person that is nonconsensual.16 It may include sexual assault, sexual coercion, verbal and physical sexual advances, and indecent exposure. Sexual abuse also occurs if an elderly individual is incapacitated and therefore incapable of giving informed consent.

Emotional or psychological abuse is defined as intentional infliction of suffering, pain, and distress through verbal or nonverbal means.16 Emotional abuse may include such acts as insulting or demeaning comments, name calling, threats of deprivation, isolation, and humiliation. Emotional abuse may accompany physical abuse or other forms of abuse.

Neglect is defined as the failure or refusal of caregivers to fulfill any of their duties or obligations to an elderly individual, which has resulted or is likely to result in serious harm to the elderly individual.16 Neglect is the most common type of elder abuse.18 Neglect may be either unintentional or intentional. However, intent is often very difficult to prove. Unintentional neglect may result from the inability of the caregiver to carry out responsibilities because of physical or mental inability or a lack of knowledge of how to care properly for the elderly individual. Neglect may consist of withholding of food, water, clothing, shelter, medications, medical equipment (e.g., walker, cane, glasses, hearing aids, dentures), or medical appointments.

Abandonment is defined as the desertion of an elderly person by the caregiver, custodian, or an individual who is responsible for providing care.16 As many emergency physicians are aware, elderly patients may be abandoned in the emergency department. One survey reported that a median of 24 elderly patients were abandoned annually per emergency department, with 46% living alone and no longer being able to look after themselves and 41% being left in the emergency department by family members or a caregiver.19 Abandonment may be considered a form of neglect.

Financial or material exploitation is defined as the illegal or improper use of an elderly person’s money, property, or assets.16 Financial exploitation includes denying an elderly person his or her home; stealing money or belongings; and coercing an elderly individual into signing contracts, changing a will, or assigning durable power of attorney to someone against his or her wishes.

In this chapter the term abuse will be used to encompass any of the types of abuse described above.

■ ETIOLOGY AND RISK FACTORS FOR ELDER ABUSE

There are several theories of the etiology of elder abuse.20 More recent focus has been directed toward the abusing relative or caregiver. The social learning or transgenerational violence theory proposes that children who grow up in an abusive household may go on to be abusive against their own children and perhaps parents. Another theory, the stressed caregiver theory, proposes that as a caregiver becomes increasingly stressed (from caregiving or other causes), elder abuse is more likely to occur. Some researchers theorize that it is the psychopathology of the abuser that leads to elder abuse. Proponents of the isolation theory contend that as elderly individuals become more socially isolated as a result of illness, disability, and age, they are at increased risk for abuse. Those who adhere to the dependency theory believe that increasing frailty is the underlying etiology for elder abuse, whereas others contend that frailty only prevents many elders from protecting or defending themselves and the true etiology lies with the abuser.21 It is now recognized that no single theory can account for all situations of abuse or neglect. An integrated theoretical model may describe all potential factors involved, and each circumstance may involve some components to a greater degree than others.21

Although numerous risk factors for elder abuse have been proposed, research is lacking and the list is far from definitive (Table 66-1). Therefore, emergency providers should be alert to the possibility of abuse among all elderly patients. Risk factors for elder abuse may be divided into four main categories: caregiver risk factors for abusing, elder risk factors for being abused, environmental risk factors, and institutional abuse risk factors.

■ CLINICAL FEATURES

In addition to the risk factors stated previously, other findings suggestive of elder abuse are abandonment of the patient in the emergency department by the caregiver, frequent visits to the emergency department, lack of compliance with medical appointments and medications, and the use of numerous phy-

| Financial dependence on the elder | Aggressive behavior | Caregiver separately and alone. | Elderly patients are four times more likely to present to the emergency department by ambulance than nonelderly patients. When elders present to the emergency department by ambulance, the emergency medical technicians or paramedics may be invaluable in identifying at-risk elders on the basis of their assessment of the home situation and the family dynamics at the home. Prehospital care providers should be questioned about the cleanliness and upkeep of the home; the availability of electricity, heat, water, and sanitation; infestation by rodents or vermin; and the safety of the interior of the home for the older patient. The American Medical Association (AMA) has recommended that all health care providers routinely ask their older patients about abuse, even in the absence of signs of abuse. Patients should always be questioned in as private a situation as possible, after the family or caregiver has left the room. If the patient suffers from dementia or is unable to answer questions for other reasons, individuals who have knowledge about the patient, other than the caregiver, should be questioned, such as other family members, visiting home nurses and assistants, therapists, primary care physician, or neighbors. If a translator is needed, someone other than a family member or the caregiver should be utilized. To broach the subject of elder abuse, the emergency health care provider should begin by asking about the patient’s care in general and then focus on abuse and specific types of abuse (Table 66-2). Factors that have been shown to have a significant association with suspected elder abuse include a brittle support system, feeling lonely, expressing conflict with family or friends, alcohol abuse, short-term memory problems, and psychiatric illness. One study has determined that emergency department nurses can be trained to routinely ask older patients about neglect and appropriately refer them for care. There are now several instruments that can be used to assist medical personnel in inquiring about and identifying abuse and neglect. These tools involve direct questioning of the elder, recognizing possible physical signs, or identifying risk factors. No single test has been found to be optimal, but the use of multiple approaches may be most helpful in recognizing abuse victims. If elder abuse is identified, the patient should be questioned further about the duration and frequency of the abuse, the nature of the abuse, and whether there has been intervention or assistance in the past because of the abuse. There is increasing evidence that elder abuse is associated with adverse health outcomes, including increased dementia, depression, and premature death. Therefore, a thorough, well-documented medical history and physical examination should be performed. When the medical history of an elderly patient is taken, it should be elicited from the patient and caregiver separately and alone. Potential historical indicators of abuse are listed in Table 66-3. As part of the medical history, the patient and caregiver should be asked about routine medications. The discovery of caregivers who are unfamiliar with daily medications and other necessary medical care of the elderly patient (e.g., dressing changes) should raise the suspicion of elder neglect. If injuries are noted, the patient should be questioned about how the injuries occurred. Patients should be asked directly whether anyone has hit, punched, or kicked them. If the injuries occurred as a result of interpersonal vio-

| Financial dependence on the elder | Aggressive behavior | Caregiver separately and alone. | Elderly patients are four times more likely to present to the emergency department by ambulance than nonelderly patients. When elders present to the emergency department by ambulance, the emergency medical technicians or paramedics may be invaluable in identifying at-risk elders on the basis of their assessment of the home situation and the family dynamics at the home. Prehospital care providers should be questioned about the cleanliness and upkeep of the home; the availability of electricity, heat, water, and sanitation; infestation by rodents or vermin; and the safety of the interior of the home for the older patient. The American Medical Association (AMA) has recommended that all health care providers routinely ask their older patients about abuse, even in the absence of signs of abuse. Patients should always be questioned in as private a situation as possible, after the family or caregiver has left the room. If the patient suffers from dementia or is unable to answer questions for other reasons, individuals who have knowledge about the patient, other than the caregiver, should be questioned, such as other family members, visiting home nurses and assistants, therapists, primary care physician, or neighbors. If a translator is needed, someone other than a family member or the caregiver should be utilized. To broach the subject of elder abuse, the emergency health care provider should begin by asking about the patient’s care in general and then focus on abuse and specific types of abuse (Table 66-2). Factors that have been shown to have a significant association with suspected elder abuse include a brittle support system, feeling lonely, expressing conflict with family or friends, alcohol abuse, short-term memory problems, and psychiatric illness. One study has determined that emergency department nurses can be trained to routinely ask older patients about neglect and appropriately refer them for care. There are now several instruments that can be used to assist medical personnel in inquiring about and identifying abuse and neglect. These tools involve direct questioning of the elder, recognizing possible physical signs, or identifying risk factors. No single test has been found to be optimal, but the use of multiple approaches may be most helpful in recognizing abuse victims. If elder abuse is identified, the patient should be questioned further about the duration and frequency of the abuse, the nature of the abuse, and whether there has been intervention or assistance in the past because of the abuse. There is increasing evidence that elder abuse is associated with adverse health outcomes, including increased dementia, depression, and premature death. Therefore, a thorough, well-documented medical history and physical examination should be performed. When the medical history of an elderly patient is taken, it should be elicited from the patient and caregiver separately and alone. Potential historical indicators of abuse are listed in Table 66-3. As part of the medical history, the patient and caregiver should be asked about routine medications. The discovery of caregivers who are unfamiliar with daily medications and other necessary medical care of the elderly patient (e.g., dressing changes) should raise the suspicion of elder neglect. If injuries are noted, the patient should be questioned about how the injuries occurred. Patients should be asked directly whether anyone has hit, punched, or kicked them. If the injuries occurred as a result of interpersonal vio-
Ilence, the relationship between the patient and abuser should be ascertained. Providers should inform their patients if they are mandated to report abuse when it is disclosed by a patient. However, most states mandate reporting elder abuse even if it is only reasonably suspected. Because elders may be afraid to disclose abuse, it is important that providers reassure their patients that the goal is to provide a safer living environment for the elderly patient, not primarily to punish the caregiver. When a patient expresses fear about a report, the health care provider should give this information to Adult Protective Services in the report so that risk to the patient can be minimized.

When performing a physical examination of an elderly patient, the emergency provider should look for signs of physical abuse, sexual abuse, and neglect (Table 66-4). The provider should use clinical skill and judgment to decide whether physical findings are suspicious for elder abuse or represent pathology. Illnesses that may resemble elder abuse occur frequently in older patients (e.g., easy bruising, fractures resulting from osteoporosis or osteopenia, dehydration). Elder abuse is included in the differential diagnosis of numerous conditions that occur frequently in the geriatric population. Elderly patients with multiple clinical findings consistent with elder abuse have a higher likelihood of being victims than patients with isolated findings. In addition, injuries and medical conditions for which no underlying etiology can be determined are more likely to be a result of abuse.

During the physical examination, the general appearance (e.g., cleanliness, hygiene, and dress) and behavior (e.g., agitated, fearful, withdrawn) of the patient should be noted. The skin should be examined for unexplained bruises, particularly of the head, face, torso, back, bilateral upper arms, inner aspect of the arms, or inner aspect of the thighs. Additionally, bruising on the neck, ears, genitalia, buttocks, or soles of the feet is suspicious in an elder.32 Attention should be paid to the state on the neck, ears, genitalia, buttocks, or soles of the feet is stated, fearful, withdrawn) of the patient should be noted. The (e.g., cleanliness, hygiene, and dress) and behavior (e.g., agi­
tions for which no underlying etiology can be determined are more likely to be a result of abuse.

If there has been a recent change in the patient’s ability to ambulate, further imaging studies should be performed to rule out an occult fracture (e.g., hip fracture). A thorough neuro­logic examination should be performed with careful attention to an alteration in the patient's mental status, focal neurologic findings, and dementia. The recent development of focal neurologic deficits may be a result of blunt head trauma. Long­standing focal neurologic deficits, such as hemiparesis from a cerebrovascular accident, suggest increased needs for care of the elder. The elderly patient’s mental status should be assessed. Subtle changes in the elder’s mental status may be the only signs of ongoing abuse. Dehydration and malnutrition are the most frequent physical findings of neglect.

An elderly patient who is being emotionally or psychologically abused may display deterioration in mental health and show signs of post-traumatic stress disorder. The patient may demonstrate fear, anxiety, or infantile behavior in the presence of the caregiver and may also exhibit poor self-esteem. On questioning, the elderly patient may admit to ambivalent feelings toward the family member who is the caregiver, as well as express feelings of mistrust related to the caregiver. The caregiver may also be emotionally abusive in the presence of the emergency health care provider. Elderly patients who are being physically abused, sexually abused, or neglected may also demonstrate findings similar to those of emotionally abused elderly patients.

### DIAGNOSTIC STRATEGIES

When elder abuse is suspected, laboratory investigations and imaging studies should be obtained as indicated by the history
and physical examination. The emergency provider should have a lower threshold for ordering imaging studies for elderly patients secondary to difficulty in obtaining a history in some cases, the increased frequency of osteopenia and osteoporosis, and the tendency of some elders to minimize pain (Fig. 66-4). Metabolic laboratory tests may be helpful in determining electrolyte, nutritional, or endocrine abnormalities. Toxicologic studies may be helpful to document compliance with medications, overmedicating or undermedicating by the caregiver, and, in severe cases of elder abuse, evidence of poisoning.

**DOCUMENTATION**

Accurate and thorough documentation of the history and physical examination in cases of suspected elder abuse is essential. The history of any suspected types of abuse, as well as the mechanism of injury, should be documented in the patient’s own words, if possible. Documentation should include details of the pertinent social history (e.g., caregiver’s identity, living arrangements, functional status). A description of any injuries should include types of injuries (e.g., fractures, lacerations, and contusions), number, size, location, color, and stage of healing, or approximate ages of the injuries. When possible, photographs of the injuries should be taken before rendering treatment. In addition to photographs, the locations and types of injuries should be documented on a body map or diagram. In California, a statewide form has been developed for the purpose of documenting a forensic examination in cases of elder abuse. At this time, its use is not mandated. The explanation given by the patient for the mechanism of each injury should be included in the history, as well as whether the explanation seems appropriate. If the explanations for the injuries seem reasonable, a statement reflecting that the physical examination is compatible with the history may be included in the medical record. The results of laboratory investigations and imaging studies should also be recorded. Follow-up plans, referrals, and interventions should be documented in the medical record. If a report is made to Adult Protective Services, the name of the individual contacted or the case number should be recorded. In addition, if law enforcement is contacted, the name and badge number of the officer taking the report should be documented. In cases of suspected elder
abuse that result in legal action, thorough documentation may be critical in determining the outcome and ultimate care of the patient.

**CAREGIVER INTERVIEW**

Part of the assessment of a suspected victim of elder abuse involves interviewing the caregiver or suspected abuser. The needs of both the caregiver and the elder should be addressed. To obtain beneficial information and not create a confrontational situation with the caregiver or suspected abuser, questioning should proceed in a nonthreatening and nonjudgmental manner. The goal is not to punish the caregiver but rather to stop the abuse. Accusations are likely only to curtail the amount of information the caregiver provides to the emergency physician. The caregiver or suspected abuser should be interviewed separately from the patient. Conducting separate interviews may reveal discrepant histories between the caregiver and the patient. Initially, questioning should be directed at the reason for presenting to the emergency department. Subsequently, questions should be directed at the patient’s medical conditions and the daily care requirements, including routine medications and assistance with activities of daily living. Caring for an individual with chronic illness who frequently requires assistance with basic activities of daily living is a difficult and tiring task. Therefore, verbal expressions of sympathy, explicit recognition of the challenges, and demonstrations of support can be beneficial for the caregiver and also promote information sharing. Statements such as “Caring for your mother must be a difficult task. Do you ever feel anger or resentment toward her?” may actually allow the family member or caregiver to express valid frustrations. Questions should also explore whether any recent stresses have occurred in the household, whether the caregiver feels that the patient is a financial burden, and whether any respite services or other home help services have been made available.

**INTERVENTIONS AND REFERRALS**

When elder abuse is suspected or identified, provision for immediate care needs, situational assessment, long-term care planning, and steps to prevent future abuse are all required. Emergency department interventions in elder abuse differ from those in child abuse primarily because the physician must respect the wishes of the mentally competent elderly adult. The older adult should be able to live in the least restrictive environment possible, and institutionalization should not automatically be regarded as a solution to ending the abuse. For many elders, the prospect of being institutionalized is worse than continuing to live in an abusive situation. In addition, providing home care assistance, respite care, and other in-home resources to the caregiver and elderly patient is more cost effective than institutionalization. Therefore, one of the goals of management of elder abuse is to keep the family unit together, when possible, rather than have the elder removed from the home.

If there is immediate danger, the patient should be prevented from having any contact with the suspected abuser, which may involve being removed from the home. Hospitalization may be required for injuries and ongoing medical problems. However, in the absence of an acute medical illness, medical insurance companies and third-party payers may not cover the cost of hospitalization, and a safe-house placement may be required. Physicians should be aware of the diagnosis and diagnostic codes that should be used in cases involving suspected or confirmed elder abuse and neglect, Adult Maltreatment (unspecified) (ICD-9: 995.8; ICD-10: suspected T76.91, confirmed T74.91) and the additional codes for specific types of abuse.

If the patient refuses intervention, the emergency provider must determine whether the patient is capable of making his or her own decisions. In some instances a psychiatric consultation for the determination of capacity may be required. If the elderly patient is found not to have the capacity to make his or her own decisions, Adult Protective Services should be notified to arrange court-ordered guardianship. The wishes of a competent elderly patient must be respected even if the patient desires to return to an abusive situation.

In suspected cases of elder abuse that pose a less imminent threat, interventions should be individualized. If the patient wants to return home and may be safely discharged from the emergency department, a follow-up plan should be established. This is best accomplished by a multidisciplinary team consisting of the patient’s primary care physician, nurses, social workers, and occupational therapists or a geriatrics assessment team. Another approach includes Adult Protective Services caseworkers as members of the geriatric team. The follow-up assessment should consist of an evaluation of the patient’s functional, cognitive, medical, and emotional status. Social and financial resources should also be determined. The frequency, severity, and intent of the abuse should be assessed. At least one home visit should be included as part of the assessment.

The needs of the caregiver should also be assessed. Support services such as in-home services, respite care, psychological
counseling, employment referrals, and alcohol and drug abuse rehabilitation program referrals should be provided, as needed. For the short term, the emergency health care provider may assist the caregiver by obtaining increased involvement from other family members or friends, close follow-up with the patient’s primary care physician, a social services consultation, home nursing assistance, and the involvement of Adult Protective Services. Other referrals that may be beneficial for both the elderly patient and the caregiver include senior centers, medical transport services, Medicare referral, Meals-on-Wheels, senior’s housing, Social Security benefits, religious communities, home health, adult day care, hospice care, and victim assistance. Addressing behavioral issues in the elderly may also be very helpful to an overwhelmed caregiver. Ultimately, if the caregiver has severe personal problems that cannot be resolved, the only solution may be separation of the elder from the caregiver. If the elderly patient is competent and does not wish to accept interventions, he or she should nonetheless be educated about elder abuse and given referral materials. Some cases of elder abuse are actually intimate partner violence, committed by the elder’s spouse. In these cases, intimate partner violence advocacy services should be consulted.

Elderly victims should be educated about elder abuse and the likelihood that it will increase in frequency and severity over time. All emergency departments should have protocols for the management of suspected cases of elder abuse to facilitate management and ensure appropriate care for these elderly patients. This recommendation has been made by the AMA, the American College of Emergency Physicians, and other professional medical organizations. Some emergency departments also have access to in-house elder abuse response teams that can be mobilized to assist the emergency physician with the management of these complex cases.

**REPORTING REQUIREMENTS**

In all 50 states and the District of Columbia laws have now been enacted that pertain to the reporting and investigation of elder abuse. However, the definitions of elder abuse and requirements of the laws vary from state to state. In most states, physicians are mandated to file a report if they know or reasonably suspect that elder abuse has occurred, and in several additional states physicians are mandated to report only if the suspected victim resides in a nursing home. Many of the states with mandatory reporting requirements also grant immunity to physicians who report suspected elder abuse. Most state laws also have a penalty for failure to report. These penalties usually consist of a fine or a jail sentence, or both. In most states, Adult Protective Services is designated as the agency responsible for receiving and investigating all reports of suspected elder abuse. The laws vary widely concerning the age at which “elder” is defined, with most states defining it as 60 years or older. In addition, the laws vary in their definitions of the circumstances of the abuse, types of abuse, the reporting and investigation of the abuse, and specifics regarding domestic and institutional abuse. Additional criminal laws regarding assault and battery, theft, fraud, rape, and murder may also pertain to elder abuse. Laws concerning guardianship and conservatorship, durable powers of attorney, intimate partner violence, and family violence may also be related to elder abuse. Emergency providers should become familiar with state laws pertaining to elder abuse and their duty to report in the state in which they practice.

There are several issues regarding the mandatory reporting laws for elder abuse. Some physicians are concerned that reporting elder abuse constitutes a breach of confidentiality with their patients. Others are concerned that mandatory reporting may deter elders from seeking medical care. The AMA has stated that health care providers should inform their patients if they have a legal obligation to report elder abuse and the medical necessity to intervene in cases of elder abuse. The AMA also emphasizes that the goal is to end the abuse by facilitating access to resources for the patient and their family. There is a great need for standardization of legislation and increased funding to provide adequate service delivery to elder abuse victims and their families.

Elder abuse is often underrecognized or underreported by emergency physicians. Reasons include a lack of awareness of the prevalence of elder abuse, ageism (discrimination against the elderly), lack of knowledge of the appropriate management of suspected elder abuse, lack of an emergency department protocol for suspected elder abuse, lack of time to conduct a time-consuming evaluation of the suspected abuse, the emergency physician’s concern about litigation, the emergency physician’s concern about having to take time away from the practice to testify in court, and the ethical issue of not wanting to breach physician-patient confidentiality. One study found that only 2% of reports of elder abuse were made by physicians. Physicians were most likely to report physical abuse and least likely to report exploitation. It is unclear whether this was due to underrecognition of the abuse by the physicians or the use of other team members in making the report of abuse.

Elderly patients may also contribute to the difficulty in identifying elder abuse, willingly or unwillingly, because of isolation resulting from illness or age; inability to report abuse; reluctance to disclose the elder abuse owing to embarrassment or guilt; fear of retaliation by the abuser; wanting to protect the abuser, who is often a spouse or a child; fear of the consequences of the discovery of the abuse; fear of institutionalization; cultural or ethnic beliefs and backgrounds; and feeling that they are a burden to their families.

**INSTITUTIONAL ABUSE**

Approximately 5% of all elderly individuals reside in institutions such as nursing homes, board and care homes, and other assisted-living facilities. With the growing elderly population, this percentage is estimated to increase significantly in the future. In 1976, the Older Americans Act established the Long-Term Care Ombudsman Program to monitor nursing homes and board and care facilities and to investigate cases of suspected elder abuse. This program is present in all 50 states. In 1987, the Nursing Home Reform Act included the right to be free from physical, sexual, and emotional abuse as well as isolation. Elderly residents of institutions may be subjected to abuse by other patients, visitors, and staff. A random survey of staff in long-term care institutions in one state revealed that 10% of nurses’ aides reported committing at least one act of physical violence in the previous year and 40% at least one act of psychological abuse. Risk factors for institutional abuse are shown in Table 66-1. A study examining ombudsman data from six states found that a higher percentage of complaints lodged on behalf of minorities were verified, but a lower percentage were fully resolved. When patients from long-term care facilities present to the emergency department for medical care, emergency providers should be alert to signs of possible abuse. These cases should be reported to the state long-term care ombudsman for further investigation.

**ABUSE OF PERSONS WITH DISABILITIES**

In most states, the laws protecting elders from abuse also protect persons with disabilities, often referred to as
“dependent adults,” “vulnerable adults,” or “disabled adults.” Included are persons aged 18 or older who have developmental, mental, or physical disabilities. Little is known about abuse and neglect of persons with disabilities; however, adults with disabilities are reported to be at higher risk for abuse than persons without disabilities. In particular, persons with developmental disabilities are at high risk for abuse. The best conservative estimate is that people with developmental disabilities are four to ten times more likely to be victims of crime (or abuse) than people without disabilities; the most pronounced are robbery (12.7 times higher) and sexual assault (10.7 times higher). Emergency providers should have a heightened awareness of the greater likelihood of abuse when managing patients with disabilities and understand the mandated reporting laws and resources available to disabled victims in their state.

**FUTURE DIRECTIONS**

Residency training should include education in identifying and managing elder abuse and the reporting requirements for elder abuse. Emergency providers should also educate their patients and the community about the problem of elder abuse and the resources available in the community to assist elders and their caregivers. They should advocate for increased availability and funding of in-home services for elders. Further, they should engage in research on elder abuse to increase the understanding of risk factors for elder abuse, develop validated questions for the detection of elder abuse, determine effective management protocols, and evaluate effective preventive interventions.

- Emergency health care providers should routinely ask all elderly patients about abuse, even in the absence of signs and symptoms of abuse. All emergency providers should be alert to the possibility of elder abuse.
- The needs of the caregiver should be assessed and support offered.
- An elderly patient who is in immediate danger should be hospitalized or prevented from having any contact with the suspected abuser, which may involve being removed from the home. If the patient is not in imminent danger, assistance may be provided to the caregiver. The family unit should be preserved whenever possible.
- The wishes of a competent elderly patient must be respected, even if the patient is not willing to accept interventions.
- In most states emergency physicians are mandated to report cases of known or suspected elder abuse to Adult Protective Services.
- The diagnostic term “Adult Maltreatment” should be used in cases of suspected or confirmed elder abuse or neglect. The use of this ICD diagnosis may facilitate hospitalization, if necessary, and will improve the accuracy of clinical prevalence data.

Chapter 67  Youth, Street Gangs, and Violence

H. Range Hutson and Jared Strote

Perspective

Presently, there are approximately 82 million children and adolescents under the age of 20 in the United States. This population is increasingly composed of older adolescents and ethnic minorities. Adolescents are particularly vulnerable to violence and injury because of developmental issues, including independence and autonomy, curiosity leading to experimentation (e.g., alcohol, drugs, sex), peer group pressure, immaturity, impulsivity, the feeling of invincibility, narcissism, and problems with self-identity. Other factors that increase the vulnerability of adolescents to violence include the breakdown of family and community structure, media violence, and easy accessibility to lethal weapons (e.g., firearms). Data from the Federal Bureau of Investigation estimate that 16% of violent crimes are perpetrated by youths under the age of 18 years.

Contrary to popular belief, violence is a learned behavior, and is predictable and preventable. A child's initial exposure to violence usually occurs in the home (e.g., intimate partner violence, child abuse, elder abuse, corporal punishment) and increases an adolescent's predisposition to violence. The degree to which adolescents are exposed to violence in the home, community, school, media, sports, and peer groups and the extent to which they are victims of violence are associated with their own use of violence. Except for rape, adolescent males are exposed to more violent acts than females and perpetrate more violence than females, with inner city youth having greater exposure to violence than others.

Historically, injuries have been mistakenly called “accidents” because they have been viewed as unpredictable and uncontrollable. Epidemiologic research now shows that injuries, like other diseases, occur in highly predictable patterns and are controllable and preventable. Every year in the United States, approximately 16 million children and adolescents are treated in the emergency department (ED) for injuries, 600,000 are hospitalized, and 30,000 sustain permanent physical and neurologic sequelae from their injuries.

Injury is the leading cause of death during the child and adolescent period, causing more deaths than all other diseases combined. For every death attributable to violent injury involving children and adolescents, there were 8 hospitalizations and 108 ED visits. Assault is a leading cause of injury, particularly in adolescents, and this is the most common group victimized by violent crime. Physical fighting is one of the most important risk factors for homicides, particularly for male adolescents. Homicide is the second leading cause of death for those between 15 and 24 years of age. In addition, homicide is the leading cause of death among African American males, who are six times more likely to die from homicide than white males in this age group. Further, homicide rates for children and adolescents are peaking at progressively earlier ages. Adolescents are disproportionately represented as perpetrators and victims of violent crime, while one third of individuals arrested for violent crimes (e.g., assault, rape, and homicide) are adolescents.

Violence in Schools

Many adolescents report that their greatest fear is school violence. In a national survey, 6% of students had not gone to school due to feeling unsafe at school and 6.5% had carried a weapon in the prior 30 days due to feeling unsafe at school. The study also noted that 13.6% of students had been in a physical fight on school property and 7.9% had been threatened or injured with a weapon in the prior 12 months. Although the rates of physical fighting and weapon carrying have decreased from 1993 to 2003, the availability of firearms to urban adolescents is pervasive and not limited to gangs or others at high risk for violence.

Half of all school-associated violent deaths occur during transition periods during the school day (beginning of school, lunch period, end of school day). Most firearms used in school-related deaths are obtained from the perpetrator's home.

Although other school violence is decreasing, bullying is now being increasingly recognized. Bullying is designed to intimidate or harm an individual or group of individuals. Verbal intimidation, and increasingly, electronic harassment (e.g., text messaging, social network sites) are the most common forms; however, an association with physical violence is growing. Bullying commonly starts in elementary school and continues throughout junior high and high school. Although bullying occurs among girls, it is a much larger male phenomenon, especially when it is associated with physical violence.

In the National Crime Victimization Survey, 21% of students report that street gangs are present in their schools, and they are likely to fear being assaulted in school or on their way to and from school. Gang members are seven times more likely to own a firearm than children and adolescents not in gangs. For these reasons, many children and adolescents are fearful about going to school, resulting in more weapons being brought to school for personal safety. During the 1999–2000 school
MEDIA VIOLENCE AND ITS EFFECT ON CHILDREN AND ADOLESCENTS

Children and adolescence are exposed to increasing amounts of media violence in movies, video games, youth-oriented music, the Internet, and especially television. By age 18, children have seen approximately 200,000 violent acts portrayed on television and approximately 20,000 homicides, and spend more hours watching television than attending school. When today’s children and adolescents reach age 70, they will have spent 10 years watching television. Saturday morning children’s programming still contains 20 to 25 violent acts per hour. Before age 8, children cannot consistently discriminate between real life and fantasy in entertainment. Through television and other forms of media violence, children and adolescents learn and imitate violent behavior, particularly if the aggressor is the hero or the heroine. The more realistic the violence portrayed, the greater the probability the violence will be imitated by children and adolescents. Of young men incarcerated for violent crimes (e.g., homicide, rape, and assault), 22 to 34% consciously imitated crimes learned from television. In the media, violence is a quick, effective ending for disagreements and does not show the importance of patience, negotiation, and compromise in resolving conflicts and disagreements. Media violence does not portray the true physical and psychological consequences of violent acts. This may lead children and adolescents to accept violence as a normal way of life, desensitizing them to future acts of violence and making them less likely to intervene when violent acts occur.

Media violence has consistently been associated with significant increases in aggressive and criminal behavior. The most important factors are how much violence is viewed, identification with violent characters, and the perception that TV violence is real. On television, one fourth of all violent scenes involve use of a handgun. Forty percent of top-grossing movies rated for “general audience” and “parental guidance suggested” feature at least one character carrying a firearm. Studies have shown that eighth and ninth graders who play video games frequently get into more arguments with teachers, get into more physical fights, and see the world as a more aggressive place. Further, research shows that school shootings often relate to first-person shooter video games (e.g., Doom, Halo). Studies also note the large amounts of violence in “Everyone”-rated video games. In fact, 94% of games rated for teens contain violent acts.

Short-term effects of viewing include excitement and imitation; long-term effects include desensitization to violence outcomes and socialization of violent behavior. Mediators of these effects include justification for the behavior and consequences of aggression, perceptions of realism and identification with aggressive characters, age, gender, aggressiveness and intelligence of viewer, socioeconomic status, and parental influence.

ADOLESCENTS, DRUG ABUSE, AND VIOLENCE

In the United States, 3 million adolescents have alcoholism, and another 400,000 adolescents require treatment for drug abuse. Illicit drugs cost $75 billion per year for law enforcement, incarceration, legal costs, medical treatment/hospitalization, and drug prevention programs, in addition to $70 billion per year spent for the purchase of illicit drugs. Illicit drugs account for almost half of the 1 million individuals incarcerated, requiring an enormous amount of time for law enforcement and almost 50% of judiciary work time. In youth 12 to 17 years of age, 5.4% are dependent on alcohol and 4.6% are dependent on illicit drugs; 350,000 require treatment for alcohol or drug use each year. Two million are dependent on or abuse alcohol or drugs.

From ages 10 to 13 years, children begin experimenting with a wide range of new behaviors. Cigarettes, alcohol, and other types of drugs are a normal part of the “coming of age” for many children, regardless of race, culture, socioeconomic status, or geographic location. Substance use follows a predictable pattern, beginning with experimentation with cigarettes and alcohol, followed by marijuana, then cocaine. Other drugs, including opioids and hallucinogens, typically occur later in the sequence. This does not mean that an adolescent necessarily progresses beyond a particular stage. Initially, the adolescent associates drugs with euphoria and pleasure. With regular use, tolerance and the need for particular drugs develop. At this stage, the adolescent is drug dependent and now uses the drug to prevent withdrawal symptoms, which may be physiologic or psychological in nature. For adolescents, any use of a drug is commonly perceived as drug abuse. Adolescents at greatest risk for lifelong substance abuse typically begin using drugs before age 15. Adolescents who are the most seriously affected by substance abuse are usually those who are least involved in school or other meaningful activities.

The precise relationship has not been completely elucidated, but drugs and violent behavior are related to drug use (pharmacologic violence), to drug procurement (economic violence), and to the illicit sale of drugs. Alcohol is the most commonly used drug associated with violence. The pharmacologic effects of alcohol contribute significantly to the prevalence of adolescent fighting, suicide, homicide, unintentional injury and death, rape, and physical assaults. Cocaine, barbiturates, phencyclidine (PCP), amphetamines, and anabolic steroids also play a role in such violence. Medications used for attention deficit disorder, hyperactivity, and the like are increasingly available for abuse. Economic violence can lead to intentional injury and death during the process of obtaining money to finance drug use. The illicit sale of drugs leads to several types of violence between buyers and sellers: robbery for money or drugs, arguments over quality or quantity of the drug, competition for territory or markets for the sale of drugs, and violence as a management strategy to discipline drug-selling subordinates.

FIREARMS

In the United States, eight children and adolescents are killed every day by firearms. For every child killed, three children sustain a firearm-related injury. Sixty percent of firearm assaults are fatal, compared with 4% of knife assaults and fewer than 1% of assaults with blunt objects. There are approximately 218 million privately owned firearms, of which 85 million are handguns. Handguns are involved in most firearm injuries and deaths, although they make up less than one third of all firearms. About half of all households in the United States contain a firearm. Most privately owned firearms are purchased with the idea that firearms increase personal safety and home security, but the risks of firearms kept in the home are often unrecognized. A firearm in the home is 43 times more likely to kill a family member or friend than an intruder. When a gun is fired in the home by an adolescent, the victim...
most often is the adolescent (35%), a friend (34%), a sibling (25%), or a parent or relative (6%). Many firearms in the home are stored unlocked and loaded. In one survey, three fourths of children younger than 14 knew exactly where the firearm in their house was located and one third had handled it. Before 8 years of age, few children can distinguish between a toy gun and a real gun. Before 8 years of age, few children can distinguish between a toy gun and a real gun. Before 8 years of age, few children can distinguish between a toy gun and a real gun. Before 8 years of age, few children can distinguish between a toy gun and a real gun. Before 8 years of age, few children can distinguish between a toy gun and a real gun. Before 8 years of age, few children can distinguish between a toy gun and a real gun.

Death caused by firearms occurs 90 times more frequently in the United States than in any other industrialized nation. The availability of firearms increases the lethality of violent behavior, and easy accessibility plays a major role in the morbidity and mortality of children and adolescents. In the past 20 years, there has been a 75% increase in child and adolescent firearm deaths. The firearm homicide rate for boys is three to four times that for girls. The firearm death rate among U.S. children age 14 and younger is approximately 12 times greater than the firearm death rate among children in 25 other industrialized nations combined. Firearm homicide rates are highest among African American adolescent boys in urban areas in the United States. For African American male adolescents, firearm injury is the leading cause of death. Among adolescents, homicides occur most often in urban areas, and suicides occur most often outside urban areas. Among children, those in the most deprived socioeconomic quintile had a 159% higher homicide rate compared with those in the least deprived quintile. A handgun is the weapon used in 82% of adolescent homicides; most adolescent homicides are not premeditated but are impulsive, unplanned, and, in most cases, instantly regretted.

NONPOWDER FIREARMS

Modern technology has transformed the BB gun from a toy to a potentially lethal weapon with a muzzle velocity in the range of small-caliber, low-velocity powder firearms. Other nonpowder firearms include pellet guns and air pistols that use spring-loaded, manual pump compression or pressurized carbon dioxide instead of gunpowder and can cause severe injury or death at close range.

Nonpowder firearms are used predominantly by children and adolescents, with 80% of all injuries by nonpowder firearms in these age groups. These injuries account for 23,000 ED visits per year. Victims of nonpowder firearm injuries are overwhelmingly male. Injuries to the extremities are the most common, with 33% of injuries to the eyes, head, face, or neck. The most serious injuries are intracranial penetration in the region of the orbit or thin regions of the skull. Nonpowder firearm injuries are a common cause of blindness in adolescent boys; other complications include embolization and lead poisoning. Penetration of the heart and aorta occasionally results in death. Overall, nonpowder firearm injuries are more numerous and less severe than powder firearm injuries, but head, chest, and abdominal wounds from these weapons may be erroneously regarded as trivial, with catastrophic results.

PREVENTION STRATEGIES FOR YOUTH VIOLENCE

Children and adolescents lack judgment and experience and cannot be expected to avoid violence and injury by their own accord. Factors associated with youth violence include history of violence victimization, exposure to violence, access to weapons, substance abuse, antisocial beliefs, low parental involvement, low income, poor academic performance, social rejection, low levels of community participation, and high levels of community transience. Factors associated with protection from violent behavior include high grade point average, strong religious beliefs, connectedness to family, ability to discuss problems with parents, and large amounts of social capital in the community. To identify youths at risk for violence, physicians should screen for these risk factors. Many medical associations, including the American College of Emergency Physicians, have policy statements calling for physicians to incorporate youth violence prevention into their practices. To decrease youth violence, physicians and other health care providers should urge the media to do the following: (1) decrease the violence, use of weapons, and pain and suffering depicted in the media; (2) accurately portray the true consequences of violent acts; and (3) decrease the amount of violent lyrics and violent scenes in music videos and video games. Physicians should advise parents to monitor and limit their children’s viewing of television, video games, music videos, movies, and the Internet.

Health care providers can encourage schools to address youth violence. Schools should be encouraged to teach conflict resolution and anger management skills, which represent an empowering step toward avoiding violence. Further, schools can make the learning environment physically safe by decreasing weapons among students. Students should be advised of the risk and legal consequences of carrying weapons to school. Depending on the school and local community, metal detectors and school safety police may be necessary. Schools should work jointly with local communities to decrease violence that occurs on the way to and from school and the overall level of violence in the community. Emergency physicians and other health care providers should encourage school-based counseling concerning violence and injury prevention.

This may be a cost-effective method of preventing childhood and adolescent violence. Physicians should educate children, adolescents, and their parents about drug use leading to abuse and dependency and the association between drugs and violence. Physicians should educate parents about the risk of firearms kept in the home and, if a firearm is present, the proper storage, i.e., unloaded, separated from ammunition, and in a locked box or cabinet. Parents should ask about firearms when their children visit other homes and allow their children to use nonpowder firearms only with goggles, chest protection, and adult supervision.

The hospital and ED medical records of victims of violence should include the circumstances of the violent event leading to the injury. The emergency physician should also document the victim’s relationship to the perpetrator of the violent event, the use of alcohol or drugs by the victim, and whether the victim has a previous history of injuries caused by violence. Most importantly, the emergency physician should determine whether the victim plans to seek revenge and provide immediate counseling emphasizing a cooling-off period to prevent further acts of violence. The risk of reinjury or death to the patient and others and the risk of criminal prosecution should be discussed. Health care providers should check with local laws to determine if they may be legally bound to report to law enforcement officers if the patient threatens a specific individual. All individuals at risk for reinjury caused by violence should be counseled by either health care providers or social services while in the ED.

VIOLENCE BY STREET GANGS

Street gangs are mainly composed of inner-city adolescents from the same socioeconomic background. Adolescents join street gangs for a sense of belonging, protection, status, adventure, and illegal monetary gain. The vast majority of inner-city youth do not join street gangs.
In the 1950s, street gang violence typically involved fist-fights, blunt objects, knives, and occasionally firearms. There was a much lower probability of serious injury or death to gang members or innocent bystanders. Modern-day street gangs are larger, more numerous, more widespread, more violent, and no longer confined to the inner city. More gang members and innocent bystanders are injured or killed since firearms have become the weapons of choice.\textsuperscript{83} Drug use and selling, violence, and vandalism significantly increased the likelihood of joining a gang.\textsuperscript{84} Gang members, as the ultimate defenders of intrusions in their neighborhood or on their turf by rivals, are willing to die, risk imprisonment, kill rivals, or unintentionally injure or kill innocent bystanders. If a rival street gang insults, challenges, injures, or kills a member of another street gang, it is highly probable that an episode of violence will occur. Being injured, imprisoned, or killed defending the gang or turf often enhances a gang member’s reputation and standing in the gang. The more violent the street gang, the greater the reputation of the gang members. Gang members commonly do not testify in court against rival gang members but prefer to enforce their own brand of justice, violently, against rival street gangs. Common reasons for street gang violence include retaliation for previous shootings, rivalry, turf fights, arguments, and, at times, control over an illegal criminal enterprise. Injuries and homicides by violent street gangs occur in many ways, including walk-up shootings, drive-by shootings, stabbings, use of blunt force weapons, and arson. In most instances, street gang violence is intraracial (e.g., African American vs. Hispanic American, Hispanic vs. Hispanic).

Violent street gangs are active in 94\% of U.S. cities with a population greater than 100,000,\textsuperscript{85} yet are also present in many small cities and towns. It is estimated that there are 26,000 gangs and approximately 840,000 gang members nationwide.\textsuperscript{86,87} Modern street gangs nationwide have patterned themselves after the street gang subculture in the Los Angeles area (African American street gangs [e.g., Crips, Bloods] and Hispanic street gangs). The street gang subculture has created its own style of dress, form of verbal and nonverbal communication, music, camaraderie, and funeral rituals, which has made it possible for adolescents of any ethnic group or background to identify with the gang lifestyle.\textsuperscript{88,89} There are African American, Hispanic, Asian, and white gangs. Some white gangs differ from other ethnic gangs in that they are consistently involved in acts of hate violence.\textsuperscript{87}

Life in the gang typically begins around age 13 as a “wannabe,” with most adolescents joining the gang at around age 15. The peak ages for violent street gang activity are between 15 and 21 years,\textsuperscript{89} after which gang members begin to migrate out. Some members stay active in the gang into their early 30s.\textsuperscript{91}

The most likely reasons for increasing gang violence include the growth in the number of gang members, the appeal of the bravado and violent image of gang members, greater levels of intergang violence, an increase in the sophistication of firearm weaponry in gang violence, an increasingly violent society, increased economic despair in urban communities, a breakdown in sociocultural institutions, and an increase in marginalization of urban children and adolescents.\textsuperscript{92–94}

**Drive-By Shootings**

One of the most common violent acts committed by street gangs is the drive-by shooting, defined as gang members shooting at suspected rival gang members from a vehicle. Violent street gangs perpetrate more than 90\% of all drive-by shootings. The primary purpose of a drive-by shooting is to create fear, terror, and intimidation among members of rival street gangs. The secondary intent is to kill.\textsuperscript{95} Drive-by shootings mainly occur at night in the inner city and generally last 5 to 15 seconds.\textsuperscript{91} Most frequently, drive-by shootings occur on public streets, with gang members shooting into cars of suspected rival gang members. Drive-by shootings also include shooting into the homes of suspected rival gang members, in parks, and around public schools.\textsuperscript{86} In many drive-by shootings, gang members flash their gang hand sign (a form of nonverbal gang communication) and yell their gang name. This makes it known to all rival gang members which gang actually was shooting at them. Most drive-by shooters are not apprehended by law enforcement.

Drive-by shootings are not random events.\textsuperscript{96} No longer confined to the inner city, drive-by shootings are now a national phenomenon and in some regions of the United States have become endemic.\textsuperscript{97} Drive-by shootings are a major public health problem because many individuals can be injured or killed in one incident.\textsuperscript{98} In one study, 63\% of children and adolescents who were shot at sustained a firearm injury, and 5.3\% died from their injuries. Thirteen people are injured for each individual killed in a drive-by shooting.\textsuperscript{96} For adolescents and young adults, the lower extremity is the most frequently injured body region, followed by the upper extremity. The most frequent fatal injuries are to the chest and head.\textsuperscript{96} Small children who are victims of drive-by shootings frequently sustain fatal firearm injuries to the head, neck, and chest. Most small children injured or killed in drive-by shootings are unintentionally caught in the crossfire of gang shootings.\textsuperscript{99}

The weapon of choice in a drive-by shooting is a 9-mm semiautomatic handgun. Some semiautomatic handguns may fire 15 or more bullets before reloading. The high-capacity, rapid-fire mechanism of a semiautomatic firearm helps to explain why many individuals may be injured or killed in a single drive-by shooting.\textsuperscript{91}

**Firearms and Violent Street Gangs**

For many gang members, firearms fulfill the need for power, status, protection, and progression from adolescence into adulthood that is no longer being met by traditional sociocultural institutions. Firearms are used in 95\% of gang homicides\textsuperscript{83} compared with 70\% of all homicides.\textsuperscript{100} Handguns—particularly semiautomatic handguns—are the most commonly used weapon in gang shootings, followed by shotguns, which are used in 8\% of all gang homicides.\textsuperscript{84} Rifles are involved in 5\% and assault weapons in 3\% of gang homicides.\textsuperscript{83}

**Psychological Effects of Street Gang Violence on Children and Adolescents**

Some urban communities have higher exposure to street gang violence than others.\textsuperscript{9,101} In one group of inner-city adolescents, nearly 85\% had witnessed at least one violent act, and 43.4\% had witnessed a murder.\textsuperscript{102} Children and adolescents living in the inner city are exposed to chronic, pervasive violence rather than isolated episodes of violence. The reactions of these children to this pervasive violence are consistent with those of children and adolescents living in war zones.\textsuperscript{103} On exposure to repetitive or extreme acts of violence, children and adolescents may show signs of sleep disturbance, difficulty concentrating in school, flashbacks, hypervigilance, increased risk-taking behavior, and a nihilistic, fatalistic orientation to the future.\textsuperscript{104} Many of these children may also suffer from post-traumatic stress disorder. The severity of a child’s or adolescent’s reaction to a gang shooting is related to the proximity to the shooting, the threat to the child or adoles-
Preventing Gang Violence in the Emergency Department

With the increase in gang violence nationwide, emergency physicians and other health care providers have become vulnerable to injury and death resulting from gang incidents in the hospital environment. The development of guidelines for the prevention of gang violence is recommended to safeguard emergency physicians, other health care providers, patients, and visitors.

In the past, recognition of local street gangs was determined by tattoos, “colors” (e.g., blue for Crips, red for Bloods), typical clothing (e.g., baggy pants, athletic team jackets), and accessories (e.g., sneakers, caps, belt buckles, bandannas), in addition to hand signs. This style of clothing and tattoos has now become popular in all segments of society, however. Information about local gangs may be obtained from community activists involved in gang prevention programs or local law enforcement agencies. All health care providers should know the root causes of violent street gang formation, the effects of gang violence on the community, and the prevention of street gang violence.

Emergency Department Guidelines

1. On the arrival of injured known or suspected gang members, hospital security should be immediately involved, should be stationed in the ED and waiting area, and should secure the hospital perimeters.
2. Consistent with the primary survey examination, the patient should be undressed and searched for concealed weapons.
3. The evidence of previous major trauma (e.g., exploratory laparotomy, thoracotomy, thoracostomy scars) or tattoos may be indicative of previous gang injuries.
4. In a calm, nonjudgmental fashion, emergency health care providers should ask the patient whether he or she is a gang member.
5. ED staff should not challenge or insult known or suspected gang members. In the street gang subculture, perceived disrespect often leads to a violent confrontation.
6. While the patient is in the ED, visitation should be limited, preferably to the patient’s parents. Other visitors (e.g., friends and relatives) should be kept informed by periodic updates from the ED staff.
7. If admission is required, gang members should be admitted under “John or Jane Doe” status to protect their identity and avoid an outbreak of gang violence in the hospital.
8. Hospital security should be available 24 hours a day and should maintain high visibility and vigilance when injured gang members are present in the ED.
9. When large numbers of gang members (in particular, rival gang members) are present in the ED or waiting area, hospital security should be present and local law enforcement should be advised.
10. Although concerned for their personal safety, ED personnel should not arm themselves with firearms or other weapons while on duty. Health care providers with weapons potentially could escalate the level of violence in the ED. Gang members might view health care providers as adversaries.
11. Community leaders who are experienced with local street gangs may act as mediators between the ED staff and members of violent street gangs. These mediators should be summoned to help de-escalate any hostile situations that may arise.
12. Hospitals should have lock-down or evacuation plans for ED personnel and visitors in the event that violence erupts within the ED.
13. The ED staff should be educated in the recognition and de-escalation of prevalent aggressive behavior.
14. The ED should keep a log of all violent incidents that occur within the ED. This strategy helps to quantify the severity and use in violent incidents and could help determine the necessity for other security measures (e.g., video cameras, metal detectors, bullet-proof glass, armed safety police).

As long as gang violence exists in the community, spillover of the violence into the ED is inevitable. Although concerned about their own safety, ED personnel should deliver compassionate care to all members of violent street gangs while minimizing their own risk of injury.

Prevention of Street Gang Violence

Law enforcement and the criminal justice system alone cannot solve the violence perpetrated by members of street gangs. The United States should develop a national policy on the issue of violent street gangs, with an emphasis on alleviating the root causes of violent street gang formation. The root causes of violent street formation include poverty, stress, family, lack of education, unemployment, underemployment, racism, marginalization, and a breakdown of sociocultural institutions. Although incarceration is a part of the solution, primary prevention through alleviating the root causes of violent street gang formation would be more effective. For truces among violent street gangs to be effective, they should be supported by concerted efforts to alleviate the root causes of violent street gang formation.

Some gang members are receptive to leaving the gang after being injured or after a fellow gang member has been injured or killed in violent street gang activity. Accordingly, preventive measures to break the cycle of gang membership should occur when injured gang members present to the ED. Hospital-based interventions should begin in the ED and continue throughout their hospitalization. When discharged from the hospital, counseling should continue to intervene further in breaking the cycle of violent street gang involvement. Because many individuals in the community, particularly children and adolescents, may experience the physical and psychological effects of violence, counseling should be made readily available.

Any prevention strategy with a unilateral focus would be unsuccessful in decreasing violent street gang activity and breaking the bonds of gang membership. The solution to street gang violence should involve a multifaceted approach.

PART III

Medicine and Surgery
PERSPECTIVE AND PRINCIPLES OF DISEASE

Anatomy

The stomatognathic system comprises the musculoskeletal unit of the mandible, maxilla, and muscles of mastication; the dental unit (teeth); the attachment apparatus that anchors teeth; and other soft tissues of the oral cavity.

Musculoskeletal Unit

The mandible is formed by two rami that divide into a horizontal and an ascending portion. The horizontal portion forms the body of the mandible. The ascending ramus divides into the coronoid process anteriorly and the condylar process posteriorly. The temporomandibular articulation is unique because it consists of a bilateral joint, or diarthrosis, between the mandibular fossa and articular eminence of the mandible’s temporal bone and condyle (Fig. 68-1). An intervening layer of fibrous connective tissue separates the articulating surfaces. A fibrous capsule also surrounds the temporomandibular joint (TMJ) and is reinforced by capsular ligaments that help limit mandibular range of motion. Functionally, when the mandible opens, the condyles move inferiorly and anteriorly down the eminence; during closure, the mandible moves posteriorly along the eminence and superiorly into the fossa.

The muscles of mastication are divided into the mandibular elevators (the supramandibular group) and depressors (the inframandibular group). The elevators, or “masseteric sling,” consist of the masseters, medial pterygoids, and temporalis. The posterosuperior movement of the condyle during mandibular closure is the result of bilateral, simultaneous movement of this group. The muscles involved in the opening or depression of the mandible include the lateral pterygoid, digastric, geniohyoid, and mylohyoid. Bilateral activity of these muscles results in opening; unilateral contraction causes the mandible to deviate to the opposite side. At rest, the mandible assumes a position in which the mandibular and maxillary teeth are separated by a few millimeters of space. During functional activity, mandibular closure occurs as the action of the elevators predominates.

Teeth

The pulp is the tooth’s center and serves as its neurovascular supply. The primary purpose of the pulp is to provide sensa-
Periodontium

The periodontium consists of the gingival unit and the attachment apparatus. The gingiva is covered with keratinized, stratified, squamous epithelium and invests the tooth and alveolar bone. Apical to the gingiva is the alveolar mucosa, which is covered by nonkeratinized epithelium and is more subject to trauma. In healthy individuals, the gingiva is attached firmly to the tooth by connective tissue fibers inserting into the cementum, extending coronally from the alveolar bone to the cementoenamel junction. A 2- to 3-mm cuff of tissue, the gingival sulcus, is bordered by the enamel surface of the tooth, the gingival epithelium, and the junctional epithelium at its base (see Fig. 68-2). In a disease state, such as in the presence of the loss of alveolar bone, this cuff increases in depth and is called a “pocket.”

The attachment apparatus refers to the cementum on the tooth, the periodontal ligament, and the alveolar bone. The periodontal ligament is a fibrous structure that surrounds the root of the tooth. It is the key structure that anchors the tooth because it serves as a double periosteum that lays down cementum on the tooth on one side and alveolar bone on its other side.

Pathophysiology

Nontraumatic Dental Emergencies

Two pathophysiologic processes affect the dental health of most of the population: (1) dental caries and (2) periodontal disease. Variables related in both disease states include the oral environment, consisting of the teeth and attachment apparatus; the presence of local factors such as bacterial plaque and oral microflora, and substrate; and host states, including immunocompromising diseases and nutritional status. Factors such as water fluoridation, fluoride supplements, and plaque control techniques (e.g., flossing, brushing, and dental surgical procedures) have decreased significantly the prevalence of dental caries and periodontal disease.

Fascial Planes of the Head and Neck

The fascial planes of the head and neck are defined as potential spaces filled with loose areolar tissue that separates the layers of fascia of the head and neck. The deep cervical fascia is most important in a discussion of the extension of oral infection to the head and neck (Fig. 68-4). The deep cervical fascia consists of the superficial and investing layer, the pretracheal layer, the prevertebral layer, and the carotid sheath. The superficial and investing layer surrounds the entire neck; it splits as it attaches to the inferior border of the internal pterygoid muscles at the mandible’s ascending ramus. This split forms the masticator space. This space communicates superiorly above the level of the zygomatic arch with the superficial and deep temporal pouches.

Other spaces of importance in the neck to which dental infection may spread include the lateral pharyngeal or parapharyngeal space, which is lateral to the pharynx and medial to the masticator space; the retropharyngeal space, which is between the deep cervical and prevertebral fascia; and the prevertebral space, which is posterior to the retropharyngeal space. The pharyngomaxillary space extends from the base of the skull to the hyoid bone and is especially important because it communicates with all deep spaces.

The mandible itself may be divided further. The mylohyoid muscle divides the superior sublingual and inferior submaxillary spaces.

**Medicine and Surgery**

**Section One**

**Head and Neck Disorders**

**Figure 68-4.** Natural progression of dental infection. The pathways by which such infections may travel are (1) postzygomatic (from canine fossa in cuspid and bicuspid region; pterygomaxillary fossa communicates from rear); (2) vestibular; (3) facial; (4) submandibular; (5) sublingual; (6) palatal; (7) antral; (8) pterygomandibular; (9) parapharyngeal; (10) masseteric. (Redrawn from Rose LF, Hendler BH, Amsterdam JT: Temporomandibular disorders and odontic infections. Consultant 22:125, 1982.)

**Dental Caries**

Dental caries is a multifactorial disease involving a susceptible host, cariogenic oral flora, and a substrate. In 1890, it was proposed that caries resulted from the decalcification of enamel by the production of acids from bacteria.5-7 In the presence of saliva and a carbohydrate, cariogenic oral flora are able to develop a matrix called *dental bacterial plaque*. The bacteria metabolize the carbohydrate to form acids that decalcify the enamel. After the carious process has invaded the enamel, the microporous dentin is able to transmit saliva, by-products of the bacteria, and the bacteria themselves to the pulp. The pulp initially reacts with a hyperemic response, which continues to an inflammatory state, progressing to total degeneration and necrosis.

Pus leaks from the apex of the root and forms an abscess; this is termed a *periapical abscess*. Periapical abscesses are confined within the alveolar bone (Fig. 68-5). The abscess may break through the cortical plate of either the mandible or the maxilla and spread subperiosteally. Subperiosteal extensions are generally well confined anatomically by muscle attachments; however, if the muscle attachments are violated, either during a surgical procedure or by the natural extension of an infective process, the bacteria can gain access to the fascial planes of the head and neck.8-11

Infection extending to the submaxillary, sublingual, and submental spaces with elevation of the tongue is called *Ludwig’s angina*. Ludwig’s angina is one of the most serious mandibular infections because of its potential for airway obstruction.

Space infections also may involve the face. The canine space is bounded by the orbicularis oris, the levator labii superioris, and the buccinator; abscessed anterior maxillary teeth commonly involve this space. Infection can extend to the peri-orbital area. The most serious complication of such space infections is cavernous sinus thrombosis resulting from contamination of the (valveless) facial venous system. The buccal space is superficial to the buccinator and limited by the anterior border of the masseter; maxillary molar infection com-
commonly spreads to this space. The mental space is located at the anterior table of the mandible and often is infected by abscessed lower anterior teeth.11

- Clinical Features

Examination of the Oral Cavity

The examiner should wear eye protection, a mask, and gloves in compliance with universal precautions when examining the oral cavity. Ideally the patient should be placed in a dental/ear, nose, and throat chair or on a cart at a 45-degree angle. Because pediatric patients are unlikely to cooperate with the examination, the following technique is used by some experienced practitioners. The child is first placed in the parent’s lap facing the parent. The examiner then sits in front of the parent. While the parent gently restrains the child’s arms and legs, the emergency physician can lean the child backward and lock the child’s head between the physician’s legs.

An overhead examination light, headlight, or flashlight can be used for illumination. Other ancillary aids include a tongue depressor, 2 × 2 gauze, and possibly a dental mirror. To prevent the mirror from fogging, it should be warmed under hot water or a flame or moistened with the patient’s saliva.

Examination of the oral cavity should be systematic, beginning with the soft tissues and including the tongue. The base of the tongue is examined for lesions, and Wharton’s duct is examined on each side. The teeth should be examined next. Percussing a tooth with a tongue blade or handle of a mirror is a good way to elicit tenderness.

Radiographic evaluation of teeth is best accomplished using dental (periapical) films. These films are generally not available in the emergency department (ED), however. A panoramic radiograph is a useful alternative (see Fig. 68-5).

Signs and Symptoms

Dental Caries

Dental caries are the most common cause for pain of odontogenic origin. The patient may give a variable history of a sudden or gradual onset of a sharp to dull, throbbing pain. In most cases, the patient can indicate the specific tooth involved, but at times the pain may be generalized. An early pulpitis is sensitive to changes in temperature and aggravated by lying down; a more advanced pulpitis is worsened by any stimulus, including air. Pain may be referred to the ear, temple, eye, neck and, rarely, the opposite jaw.

Physical examination may reveal a grossly decayed tooth; however, if the carious process is interproximal or did not result in destruction of the outer table of enamel, the offending tooth may not be obvious. Localization of the involved tooth may be accomplished by percussing the teeth with a tongue blade or by having the patient bite on a piece of a tongue blade. Exquisite pain to percussion suggests an underlying periapical abscess, especially if the tooth is not sensitive to hot or cold. Palliative management is indicated for most odontalgia. Systemic analgesics, such as nonsteroidal anti-inflammatory drugs (NSAIDs) or synthetic opioid agents, are indicated. Although NSAIDs should be sufficient for most pain resulting from carious teeth, a therapeutic dental block also may be helpful. Synthetic opioids also are useful and are indicated in some cases but should not be used in chronically carious teeth without acute tooth fracture, filling crack or expulsion, or abscess because of their propensity for abuse.12,13

A dental anesthetic nerve block is helpful.14,15 A limited quantity of analgesics should be dispensed, which encourages follow-up with a general dentist.

Patients with dental pain should be examined carefully for swelling caused by abscessed teeth. A periapical abscess or a localized swelling of the gingiva adjacent to the apex of the tooth (called a parulis) may cause pain from distortion of the tissues. More commonly, fluctuant abscesses are a result of peridontal abscesses and are best treated with an incision and drainage. The gingiva and tooth are anesthetized by apical nerve block or block of the major nerve supplying the area (e.g., superior alveolar, inferior alveolar), or the gingiva is anesthetized superficially with 2% lidocaine with 1:100,000 epi-nephine. A stab incision is made toward the alveolar bone and must extend through the periosteousum; blunt dissection is carried out with a mosquito hemostat. In contrast to other abscess drainage, it is unnecessary to open the abscess from end to end—such a large incision exposes too much alveolar bone. In the dental office, a simple curettage between the tooth and the gingiva would establish drainage. For physicians not trained in dental scaling and curettage, the simple stab incision is sufficient. The cavity is irrigated, and, assuming there is sufficient space, a Penrose or iodoform drain is placed and secured with a No. 4-0 silk suture.1

The patient is started on phenoxymethylpenicillin (penicillin V) or erythromycin and warm saline rinses and is referred to an oral maxillofacial surgeon or general dentist. Drains are removed in 24 to 48 hours, and antibiotics are continued for 7 to 10 days.

The presence of cellulitis or swelling in the contiguous spaces of the head and neck indicates the spread of a localized infection. In the early stages of such an infection, the upper half of the face is generally involved, with extension of infection from maxillary teeth; cellulitis from mandibular teeth generally involves extension to the lower half of the face and the neck (Fig. 68-6). More advanced infections may extend into any of the fascial planes of the head and neck down to the mediastinum. In the nondebriditated host, untreated dental infections tend to localize and drain spontaneously and extra- orally. In the presence of a compromised host or aggressive microorganisms, spread into the fascial planes is more common, with a potential for greater morbidity and mortality. General indications for admission include suggested spread of infection to fascial planes, high fever, toxic appearance, trismus, and an immunocompromised host.

The potential sequelae of sepsis and airway obstruction must be appreciated. Computed tomography of the head and neck can be useful if the diagnosis is in doubt. Airway management should be undertaken when indicated, particularly if signs or symptoms of impending airway obstruction are present or developing (altered voice, drooling, stridor). The intubation should be approached as a difficult airway, as outlined in Chapter 1. An ear, nose, and throat specialist or oral maxillofacial surgeon should be consulted for ongoing management, including determining the site of the initial focus so that pus can be evacuated.

Signs of infection peak in 3 to 5 days. Fever usually is present. Any irritation of the internal pterygoid or masseter muscles results in trismus. Trismus is the inability to open the mouth because of involuntary muscle spasm. Trismus limits visualization of the pharynx and may make diagnosis of lateral or retropharyngeal space involvement difficult. Trismus is muscular in origin, not a result of impaired or augmented neuromuscular transmission, and so is often minimally improved or not improved at all after administration of a neuromuscular blocking agent (e.g., succinylcholine) for intubation. All patients with trismus must be presumed to be difficult
PART III
Section one • Head and Neck Disorders

ment consists of airway management as indicated, followed by admission to a unit capable of observing and managing the patient to come to the ED, unless there is sudden alarm at seeing blood on a toothbrush or the realization that certain teeth are loose. Occasionally, a patient complains about sensitivity. Clindamycin also is effective when there is a predominance of anaerobes in a penicillin-allergic patient or a patient in whom penicillin or third-generation cephalosporins seem ineffective. Potential side effects should be monitored carefully. Erythromycin is a potential alternative because it is active against most oral bacteria, but it is less active against anaerobic and microaerophilic streptococci, fusobacteria, and anaerobic gram-negative cocci. Long-term intravenous administration can also pose a problem because of its irritant effects.7

Periodontal Disease

Periodontal disease represents a continuum of pathology. Early periodontal disease is manifested by inflammation of the gingiva, termed gingivitis. Gingivitis is generally the result of an inflammatory response to an irritant, such as dental bacterial plaque and calculus. With extension of inflammation, alveolar bone is ultimately lost, a condition termed periodontitis. A physiologic space from the crest of the alveolar bone to the base of the junctional epithelium is maintained for the insertion of gingival fibers into cementum. In response to a loss of alveolar bone, the gingiva migrates down the root of the tooth, a condition termed gingival resorption. This is often accompanied by formation of gingival pockets. Advanced periodontitis results from a continuation of this process and causes marked mobility of the teeth and eventual loss as the attachment apparatus is destroyed.4,14

Space infections of the head and neck occasionally result from periodontal disease. The combination of periodontal lesions and resultant pulp pathology can create periapical abscesses with the same sequelae as those caused by dental caries alone.

Gingivitis and periodontitis in themselves rarely cause a patient to come to the ED, unless there is sudden alarm at seeing blood on a toothbrush or the realization that certain teeth are loose. Occasionally, a patient complains about sensitive teeth. The patient can be advised to improve home care and see a dentist as soon as possible.
More commonly, a patient presents with pain from a periodontal abscess or swelling of the gingiva when food or pus becomes trapped in a “pocket.” In the dental office, a periodontal abscess is treated with curettage to establish drainage. In the ED, treatment consists of a small conservative stab incision at the most fluctuant point to establish drainage, saline rinses, and antibiotic coverage. Use of tetracycline in patients older than 8 years of age is preferable because it provides better coverage for the gram-negative and anaerobic organisms found in the gingival pocket. The patient should be referred to the general dentist or periodontist for further treatment.1,3,4

Acute Necrotizing Ulcerative Gingivitis

In contrast to gingivitis, in which the gingiva becomes inflamed in response to an irritant such as bacterial plaque but is not invaded by bacteria, acute necrotizing ulcerative gingivitis (ANUG) is a periodontal lesion in which bacteria actually invade non-necrotic tissue. ANUG lesions commonly are accompanied by systemic manifestations of fever, malaise, and regional lymphadenopathy.1,3,4 ANUG is characterized by painful edematous interdental papillae. The normally pointed interdental papillae are blunted and ulcerated. A gray pseudomembrane covers the tissue and leaves a bleeding surface when removed. The lesions can involve any part of the gingiva but are more common in the anterior incisor and posterior molar regions. The patient complains of pain, a metallic taste, and foul breath (Fig. 68-7).

Gingival crevices in ANUG show a predominance of fusobacteria and spirochetes. Electron microscopy reveals a layering pattern showing fusobacteria in superficial layers with spirochetes invading in deeper layers. Other necrotizing ulcerative oral diseases, such as Vincent’s angina (extension of ANUG to the fauces and tonsils), cancrum oris (extension of ANUG to the lips and buccal mucosa, eroding through the teeth), and some pulmonary abscesses, also are caused by fusobacteria.17

Because ANUG results from an overgrowth of bacteria normally present in the gingival crevice, immunologic factors probably contribute to the disease. ANUG has been associated with immunocompromised hosts, fatigue, local trauma, emotional stress, and smoking. ANUG has the name “trench mouth” from its occurrence in large populations living in close quarters under significant stress, such as in the trenches in World War I, military barracks, and college dormitories.17 Despite this occurrence, there is no evidence that ANUG is communicable.

ANUG treatment consists of prescribing warm saline rinses; systemic analgesics so that the patient can improve oral hygiene; and systemic antibiotics, such as penicillin, erythromycin, or tetracycline. Topical local anesthetics, such as viscous lidocaine, may provide some relief. Antibiotics provide dramatic relief within 24 hours, as do dilute (3%) hydrogen peroxide rinses. Although the patient feels better, he or she should be advised to see a general dentist or periodontist for follow-up (this should be documented on the chart). The soft tissue and alveolar bone destruction from ANUG predisposes the patient to further periodontal disease; corrective procedures are necessary to create an environment conducive to maintaining periodontal health.1,3,4

Oral Pain

Although dental caries is the most common source of oral pain, the following disease entities also may cause oral or facial pain.

Root Canal Pain. Endodontic or root canal therapy involves opening the pulp chamber of the tooth, removing pulp tissue from the chamber and the root portion of the tooth to the apex, irrigating and effectively sterilizing the canal, and sealing the pulp chamber to prevent ingress of saliva and contamination. After surgery, the patient may experience exquisite pain caused by irritation beyond the apex of the tooth from instrumentation or from the buildup of gas from the irrigation solutions. Swelling may cause the tooth to be elevated slightly out of the socket so that premature contact during chewing causes extreme pain. These patients may have no relief with either systemic analgesics or anesthetic nerve blocks, presumably from the sensation of intense pressure. Treatment may consist of opening the canal to allow the gas or fluid to escape and of occlusal adjustment to take the tooth out of contact; the patient’s general dentist or endodontist may have to be contacted.18

Cracked Tooth and Split Root Syndromes. Patients with cracked teeth or a split root may report having a toothache. Pain occurs primarily with chewing or forced closure. The patient may have had an extensive dental restoration, previous endodontic therapy, or a history of having received an upward blow to the jaw. In the ED, the diagnosis is made from history and from having the patient bite on a piece of wood. In the dental office, the diagnosis is made by removing a restoration and inspecting the cavity floor. Management is similar to that for carious teeth, including symptomatic pain medication and referral back to the dentist to consider possible causes.2

Maxillary Sinusitis. Dental pain often is referred to the area of the sinuses; similarly, congested or inflamed sinuses in the proximity of the apices of the maxillary teeth may cause apparent odontogenic pain. The patient may complain of throbbing pain unrelated to changes in temperature and aggravated by lying down. On examination, there is no apparent dental cause. There may be tenderness over the maxillary sinuses or peri-orbital regions. Nasal discharge may be present. The Panorex film can screen for dental and sinus pathology.

Atypical Odontalgia

Atypical odontalgia describes dental pain for which there is no dental cause. The patient may have a history of multiple dental procedures with no relief. The pain is chronic and occurs spontaneously. Percussion may elicit pain, and there may be thermal sensitivity as if a vital tooth were present. If paroxysmal pain of neuropathic origin is excluded, atypical odontalgia can be entertained. Similar to many chronic pain syndromes, treatment with tricyclic antidepressants may be
The TMJ is a bilateral joint subject to almost continuous use. It is extremely sensitive to proprioceptive stimuli and can react to interferences in occlusion of only fractions of a millimeter. TMJ syndrome results from anatomic disharmony (see Fig. 68-1) and occlusal disturbances. The condition is aggravated by trauma, clenching of the teeth, or bruxism. Patients complain of pain in the region of the TMJ, usually unilateral. The pain is dull, worsens during the course of a day, and in extreme cases may result in trismus with palpable masseter and internal pterygoid spasm.20,23

TMJ radiographs are not helpful. Treatment consists of the external application of heat for 15 minutes four to six times per day, soft diet, analgesics including NSAIDs, and a muscle relaxant such as diazepam. Patients should be referred to a dentist specializing in TMJ disorders, such as a periodontist or a periodontal prosthodontist. Treatment at this stage consists of continued physiotherapy, bite appliances that put muscle relaxation at rest, and occlusal adjustment.24 Although certain anatomic abnormalities are amenable to surgical correction, most oral maxillofacial surgeons consider surgery only for the most intractable cases.22

**Pericoronitis**

Pain from the eruption of the third molar teeth (i.e., wisdom teeth) in an adult is common. Trapped food and plaque cause the gingiva surrounding crowded, malerupted, or impacted third molar teeth to become inflamed and swollen. This condition is called pericoronitis and is extremely painful because of repeated trauma from the opposing third molar biting on tender tissues and from distention of retromolar tissue on opening of the mandible. Pericoronitis is treated locally with warm saline irrigation, with or without hydrogen peroxide rinses. If the condition is severe or if there is a fever, an antibiotic is recommended. If fluctuant pus is present, an incision and drainage should be performed, exercising care not to track the infection posteriorly or to dissect deeply into distorted tissues, possibly encountering the internal carotid artery. Definitive treatment involves removal of the opposing third molar tooth for immediate relief and removal of the involved third molar tooth after the infection is resolved.1 These patients should be referred to an oral maxillofacial surgeon.

**Oral Manifestations of Systemic Disease**

Although the oral manifestations of many systemic diseases are nonspecific, several diseases have distinct oral presentations. In certain instances, recognition of the oral signs aids in the specific diagnosis. In other disease states, the oral condition is a contributing factor to the overall pathophysiology.25

**Diabetes Mellitus.** Oral manifestations of diabetes mellitus are associated primarily with periodontal lesions. Diabetic patients seem to be more susceptible to periodontitis. Acute gingival abscess and sessile or pedunculated gingival proliferations have been described as being caused by or intimately associated with diabetes.25

Similar to other systemic manifestations of diabetes, the degree of control of diabetes seems to correlate with its effects on the periodontium. Uncontrolled diabetes generally results in greater periodontal disease. Control of diabetes helps decrease periodontal severity, although irreversible damage, such as bone loss, may result.

Although the severity of periodontal disease in diabetic patients is a function of the response to local factors, such as plaque and calculus, there is also evidence to support the role
of vascular changes and alterations in the role of polymorpho-
nuclear leukocytes, monocytes, oral microflora, the patient’s
immune response, and genetic variables. Patients with dia-
tes who have advanced retinal changes also have been found
to have more periodontal manifestations.

Maintenance of a healthy periodontium is important in a
diabetic patient. Just as the degree of diabetic control affects
the periodontium, so too does periodontal disease affect the
degree of control. Patients with brittle diabetes or those subject
to repeated episodes of ketoacidosis might be thrown out of
control from a simple periodontal abscess. The presence of
advanced periodontal disease in a young patient, especially in
the absence of local factors, should lead one to exclude the
diagnosis of diabetes. A sudden change from a healthy peri-
donium to a diseased state suggests a similar diagnosis in an
adult. HIV infection also should be ruled out.

**Collagen Vascular Diseases.** Systemic lupus erythematosus is the
most common collagen vascular disease to have oral manifesta-
tions. Patients commonly have large ulcerated intraoral lesions
with necrotic borders. The lesions are usually secondarily
infected and painful (Fig. 68-8).

Scleroderma usually is recognized by the characteristic
facies. The periodontal ligament may appear thickened on
dental radiographs. Characteristic microscopic changes can be
seen on gingival biopsy specimens. Rare entities, such as the
midline lethal granuloma or Wegener’s granulomatosis, present
with large intraoral ulcerative lesions, usually involving the
hard palate.

**Granulomatous Diseases.** Oral manifestations of granulomatous
diseases are fairly rare today but are still seen. Tuberculosis
may give rise to lesions of the tongue or tonsillar area. These
lesions are confused most commonly with syphilitic ulcerations
or infections caused by actinomycosis. A more common
and benign entity is pyogenic granuloma, which is a prolifera-
tion of highly vascular connective tissue in response to an irri-
tant. The lesions range from sessile to pedunculated and have
a warty texture. Pyogenic granulomas in the oral cavity are
usually gingival in origin. They are especially common in preg-
nancy and are called “pregnancy tumors.” Pregnancy tumors
generally resolve 2 to 3 months after delivery; tumors that do
not resolve require surgical excision.

**Blood Dyscrasias**

The gingiva may be massively infiltrated by leukemic cells in
acute leukemic states, especially acute granulocytic leukemia.
The gingiva is edematous and bluish red and may cover the
teeth. These gingivae are compromised and may allow for the

**Drug-Induced Gingival Hyperplasias**

Some degree of gingival hyperplasia is present in 40% of
patients receiving long-term phenytoin therapy. Younger
patients seem to be affected more often than older patients.
The degree of gingival hyperplasia does not seem to be related
to dosage. The disease ranges from slight enlargements of the
interdental papillae to massive enlargement of the gingiva,
which covers the crowns of the teeth and may move the teeth.
The hyperplastic tissue is subject to infection. The presence
of local irritants seems to make the hyperplasia worse.

Treatment of the condition includes removal of local irritants
and surgical excision of the hyperplastic tissue. If the drug is
not discontinued, hyperplasia is likely to recur, although less
severely if good oral hygiene is maintained.

**Aphthous Stomatitis**

Patients may complain of recurrent small oral mucosal ulcers.
The ulcers are approximately 2 to 3 mm in size with a white
center. The lesions tend to be tender but rarely become
infected. Multiple ulcers that have coalesced can create an
impressively large lesion. One third of the population may be
affected by this condition, which is believed to be related to
stress, nutrition, oral trauma, and hormonal etiologies. The
condition is self-limiting, and treatment is symptomatic (hydro-
gen peroxide rinse; topical dental preparations such as benzo-
caine and an emollient gel; 50:50 mixture of diphenhydramine
[Benadryl] and Kapectate or Maalox; or prescription regi-
mens, such as steroid-antibiotic ointment [Kenalog in Orabase]
or sucralfate), with oral antibiotics reserved for secondary
infection. A topical sulfuric acid phenolic, Debacterol, avail-
able only by prescription, is applied to the ulcer and appears
to seal the ulcer and promote rapid healing. Ulcers that may
appear similar to aphthous ulcers are those on the soft palate
associated with hand-foot-and-mouth disease or lesions on the
gingivae and tongue from herpetic stomatitis.

**TRAUMATIC DENTAL EMERGENCIES**

**Fractures of Teeth**

The anterior teeth are commonly injured from falls or blows
directly to the teeth. Forceful blows to the mandible directed
superiorly may result in fractures of the premolars and molars
caused by a wedgelike effect of the cusps of the mandibular
teeth in the central fossae of the maxillary teeth. Many chil-
dren have an anterior overbite, which makes this part of the
dentition more prone to injury. Blunt trauma to the dentition
may result in damage to the neurovascular supply to the tooth,
bleeding within the tooth, fractures of the root or crown, loos-
Fractures of the anterior teeth are managed based on the type of fracture, its relation to the pulp of the tooth, and the patient’s age. The Ellis classification system was used to describe fractures of anterior teeth; however, now it is the accepted practice simply to describe the anatomy involved. Fractures involving enamel; enamel and dentin; and enamel, dentin, and pulp exposure traditionally have been referred to as Ellis classes I, II, and III (Fig. 68-9).

The simplest and most common dental fracture involves only the enamel portion of the tooth, leaving a chalky-white appearance. These injuries are usually minor, unless a sharp portion of the tooth causes soft tissue trauma, in which case the sharp edge may be smoothed with an emery board. The patient or parents usually are concerned about the cosmetic deformity, but they can be reassured that the tooth can be restored to its natural appearance with the use of enamel-bonding plastic materials. Referral to the dentist is necessary but not urgent.

Fractures involving the dentin have an ivory-yellow appearance. The pulp continually lays down dentin throughout the life of the tooth in response to normal and noxious stimuli. In a child, the pulp is relatively large in size, and there is less dentin; the inverse is true in the adult. Because dentin is a microtubular tissue capable of allowing bacteria to percolate into the pulp chamber, fractures involving dentin are more serious in children and adolescents as there is little dentin to protect the pulp after it is exposed to the oral cavity.

In younger patients, the management of dentin fractures involves the immediate placement of a dressing of calcium hydroxide paste over the exposed dentin covered with dry foil, a metal band or, more commonly, an enamel-bonded plastic. Early intervention may prevent contamination of the pulp and the need for subsequent root canal treatment. A pediatric or general dentist should be notified as soon as possible. Exposed dentin may be exquisitely sensitive, so the patient should avoid extremes in temperature. In an adult, who has a greater thickness of dentin compared with pulpal tissue, there is less need for urgent referral to a dentist. A dressing can be placed on the tooth for comfort. Referral should be made to a dentist for the next working day.

Fractures of teeth resulting in pulp exposure are the most serious class of fractures of anterior teeth because the pulp chamber is immediately contaminated. Care should be taken to differentiate dentin exposure from the pulp. The tooth is wiped clean with a piece of gauze and examined for a pink blush or a drop of blood, indicating a pulpal exposure. There may be excruciating pain from exposure of the nerve, or the shock of the trauma may have disrupted the neurovascular supply at the apex of the tooth, eliminating most sensitivity. This injury is often accompanied by serious fractures of the tooth, possibly involving the entire crown or root.

Pulp exposures are true dental emergencies. In the primary dentition, exposure of the pulp can be treated by performing a pulpotomy, in which the pulp in the chamber is removed, the remaining tissue is mummified with formocresol and covered with a layer of calcium hydroxide, and the tooth is restored. In most cases, if there has been minimal contamination, the primary tooth lasts its natural lifetime. In an adult, the pulpotomy is not a successful procedure, and all pulpal tissue from the crown and root must be completely removed. Although management of pulpal exposures is more urgent in a child, endodontic therapy is less complicated and more successful in an adult if there is also a minimum of contamination; in the case of a pulpal exposure from a dental fracture, a general dentist, pedodontist, or endodontist should be notified immediately if possible, or the patient should be instructed to follow up the next working day. If no dentist is available, a piece of moist cotton can be placed over the exposed pulp and covered with a piece of dry foil or sealed with a temporary root canal sealant (e.g., Cavit). Although some authors have advocated removal of the exposed pulpal tissue with a dental endodontic instrument called a barbed broach, this procedure is not recommended because this instrument breaks easily, even in the hands of a skilled endodontist. In cases of extreme pain, a dental anesthetic nerve block might be helpful.

**Subluxed and Avulsed Teeth**

Teeth that are loosened in their sockets as a result of a force are called *subluxed*. There may or may not be associated fractures. The diagnosis of subluxation can be made by gently tapping a tooth with two tongue blades. Any perceptible mobility is evidence for subluxation. A ring of blood may surround the gingival crevice. Minimally mobile teeth respond well to a soft diet for several days. Markedly mobile teeth require stabilization as soon as possible for 10 to 14 days. Teeth can be stabilized (generally by a dentist) by means of Erich arch bars, wire ligation, enamel bonding plastics, or a combination of modalities. Most of these techniques require an oral maxillofacial surgeon, hospital dentist, or pedodontist. They should be performed as soon as possible.

As a temporizing measure, the patient can bite gently on a piece of gauze, or the teeth can be stabilized for 24 to 48 hours with the application of a periodontal pack (e.g., Coe-Pak). A resin and catalyst paste are mixed together in equal quantities to a firm consistency and molded over the anterior and posterior aspects of the involved tooth and two or three adjacent teeth on each side. The patient is asked to close the mouth while the mixture hardens (Fig. 68-10). The patient is advised to avoid hot liquids that would soften the pack, eat a liquid to soft diet, and see a dentist as soon as possible.
Avulsed teeth are completely torn from the socket and are a true dental emergency. If teeth are unaccounted for, the possibility of aspiration or entrapment in soft tissues should be considered. Management of recovered avulsed teeth depends on the age of the patient and the length of time that the tooth has been absent from the oral cavity. Avulsed primary teeth in a pediatric patient age 6 months to 6 years are not replaced in the socket. Reimplanted primary teeth ankylose or fuse to the bone so that although the dentofacial complex grows downward and forward, the reimplantation site does not. There also may be interference with the eruption of the permanent tooth. Cosmetic deformity results in either case. Such patients should be referred to a pedodontist for consideration of a space maintainer or cosmetic appliance.

Avulsed permanent teeth require prompt intervention. When a tooth has been avulsed from its socket, the periodontal ligament fibers are torn; fragments remain attached both to the cementum on the root of the tooth and to the alveolar bone in the socket. Ideally, the best environment for an avulsed tooth is its socket, and it has been known since the mid-1960s that an avulsed tooth can be successfully replanted if it is returned to its socket within 30 minutes of the avulsion. A 1% chance of successful reimplantation is lost for every minute that the tooth is outside of its socket; however, there is often difficulty with immediate reimplantation. On-site personnel (parents, teachers, trainers, paramedics) may be unfamiliar or uncomfortable with tooth reimplantation. The tooth may be soiled, or the patient may be uncooperative. Occasionally, other, more serious life threats may preclude immediate reimplantation. Because of these factors, investigations were undertaken to find the ideal medium for transport and storage of an avulsed tooth.

The worst situation is to allow the tooth to be transported in a dry medium. Storage in plain water is not much better. Although saliva is a reasonable storage medium, milk is preferable because of its osmolarity and essential ion concentration of Ca$^{2+}$ and Mg$^{2+}$. The best storage and transport medium is Hank's solution, a balanced pH cell culture medium. This solution is commercially available as the “Save-a-Tooth” system (3M). Hank’s solution can maintain the viability of the cells for 12 to 24 hours or more. If the tooth has been avulsed for more than 30 minutes or has been allowed to dry, place-
ment of the tooth in Hank’s solution helps restore the periodontal ligament cells. With the “Save-a-Tooth” system, the tooth is simply dropped into the basket and the lid replaced. For removal, the lid is removed, the basket is lifted out of the solution, and the tooth is retrieved by tipping the basket over onto the padded lid.

If a call is received about an avulsed tooth, it first should be determined whether the tooth is permanent. If it is, the caller should be instructed to rinse the tooth off in saline or water and reimplant it immediately into the socket. If this cannot be performed for technical or emotional reasons, the patient should be instructed to place the tooth under his or her tongue or in the buccal pouch so that it is bathed in saliva. If the patient is too young, the tooth can be placed in the parent’s mouth. If this is unacceptable to the parent or if there is concern about aspiration or swallowing of the tooth, it should be transported in a cup of milk. If milk is unavailable, saline should be used. Ideally, the tooth should be transported in Hank’s solution.

When the patient arrives in the ED, the tooth should be reimplanted at the earliest opportunity. If this cannot be done, the tooth can be placed in Hank’s solution or a “Save-a-Tooth” system (especially if avulsion has been longer than 30 minutes or if the patient has other life threats that are being managed). If Hank’s solution is not available, the tooth is rinsed with saline, the socket is suctioned if necessary, and the tooth is immediately implanted. Local anesthesia may be necessary. The tooth should be manipulated only by the crown, if possible, so that the remaining periodontal ligament fibers are not damaged. Stabilization must be performed immediately, or the tooth will exfoliate. Stabilization is performed as described for markedly subluxated teeth (see Fig. 68-10). The status of tetanus immunization should be checked, and the patient should be treated according to the standard for a non-tetanus-prone wound (i.e., 10-year immunization update). The patient should be started on phenoxymethylpenicillin or erythromycin.

The patient is placed on a liquid diet for several days and advanced to a soft diet for 1 week. Stabilization is maintained for approximately 2 weeks, and the tooth is gradually brought into function to prevent ankylosis. Teeth that have been avulsed for longer than 30 minutes invariably require endodontic therapy. Although there may be concern about the anatomic orientation of the tooth or more confusion about which socket to use when several teeth are avulsed, each tooth should be placed into a socket with the best fit so that the tooth remains in a good physiologic environment. The dentist can make any necessary readjustments before final stabilization.

Alveolar Bone Fractures

Dental fractures and subluxated or avulsed teeth may be associated with fractures of the alveolus. Alveolar fractures may be apparent clinically from exposed pieces of bone or diagnosed radiographically. In massive facial trauma, care should be taken to conserve as much of the alveolar bone as possible, unless there is a tremendous danger of aspiration. Indiscriminate loss of alveolar bone results in tremendous cosmetic deformity that is difficult to restore with prosthetic devices. An arch bar stabilizes alveolar fractures. An alveolar fracture requires 6 weeks of stabilization for adequate healing; if there is an associated subluxed or avulsed tooth, stabilization is maintained at the expense of possible ankylosis of the tooth. The loss of alveolar bone ultimately results in more cosmetic deformity for the patient. A permanently ankylosed tooth can remain functional for some time, and although it may be difficult for an oral and maxillofacial surgeon to remove, it can be reconstructed more easily than supporting alveolar bone. The dental materials, including local anesthesia supplies and the “Save-A-Tooth” system, are conveniently assembled in a commercial package called “The Dental Box” (Dental Box Co., Pittsburgh, Penn).

Soft Tissue Injuries

Dentoalveolar trauma is commonly associated with soft tissue injuries of the lips, intraoral mucosa, and tongue. Wounds always should be examined for debris and tooth fragments. As with any surgical wound, débridement and irrigation should be performed. Final closure of soft tissue injuries should await the initial management of fractured teeth or the procedures necessary for stabilizing teeth because manipulation of the soft tissues is required. Carefully placed sutures may be torn and have to be replaced in already compromised tissue if soft tissue closures are performed first.

Gapping intraoral lacerations tend to become ulcerated, secondarily infected, and painful. Fibrotic healing results in a cumbersome scar that is subject to repeated trauma during chewing. A well-prepared mucosal wound is closed with No. 4-0 absorbable or black silk suture. Gingival and tongue lacerations are best closed with No. 4-0 black silk because this material is less irritating to the touch. Absorbable suture, such as 4-0 chromic, is excellent for children. Large tongue lacerations should be well approximated or a cleft will form during healing, necessitating a revision. Anesthesia can be achieved by either direct local injection or lingual block. Small (<1 cm) lacerations are best left alone, especially in children. The management of through-and-through lacerations involving skin and oral mucosa is controversial. With proper preparation, mucosa can be closed as described previously. Subcutaneous sutures (absorbable) are placed to close the subcutaneous tissues from the outside, removing tension from the skin. Skin is closed with No. 6-0 or No. 7-0 synthetic nonabsorbable sutures that are removed in 3 to 4 days, depending on the amount of muscle tension on the wound. Intraoral silk closures are removed in approximately 7 days.

Through-and-through lacerations and other significant intraoral wounds may benefit from prophylactic antibiotics (penicillin is the drug of choice). The patient is advised to maintain oral hygiene, use saline rinses six times a day, place a triple antibiotic ointment over the skin closure, and watch carefully for infection. These patients should be seen in 48 to 72 hours to check for infection. Normal postoperative soft tissue swelling should not be mistaken for an infected wound.

Temporomandibular Joint Dislocation

The mandibular condyles may dislocate from trauma, but more often dislocation follows extreme opening of the mandible such as occurs after a yawn or laughter. TMJ dislocation occurs when the condyle travels anteriorly along the eminence and becomes locked in the anterosuperior aspect of the eminence. The masseter, internal pterygoid, and temporalis go into spasm attempting to close the mandible; trismus results, and the condyle cannot return to the temporal fossa. Mandibular dislocation is painful and frightening for the patient. Patients prone to mandibular dislocation include individuals with anatomic disharmonies between the fossa and articular eminence, weakness of the capsule and the temporomandibular ligaments, or torn ligaments. Dystonic reaction to drugs may result in mandibular dislocation. Patients who have had one episode of mandibular dislocation are predisposed to further dislocations. If a unilateral dislocation has occurred, the
Jaw deviates to the opposite side. More commonly, a symmetrical dislocation occurs. In cases of traumatic dislocation, a mandibular series, Panorex, or TMJ radiographs should be taken to exclude the possibility of a fracture.\textsuperscript{1,42,47,49}

Reduction of a dislocated mandible is straightforward, although often difficult because the strength of the masseter contraction must be overcome. The patient requires procedural analgesia and sedation as for any other dislocation. Either facing the patient or from behind, the emergency physician grasps the mandible with both hands; the thumbs rest on the ridge of the mandible intraorally, posterior to the molars, and the fingers wrap around the outside of the jaw. It is best to have the patient sitting up, with a firm surface behind the head, so that posterior and inferior pressure can be exerted without accompanying movement of the patient’s entire head. Some physicians prefer to place the thumbs on the occlusal surfaces of the teeth; in this case, the thumbs must be wrapped with gauze to protect them when reduction is accomplished because the masseter muscles can contract with tremendous force. Firm, progressive, downward pressure is applied on the mandible to free the condyles from the anterior aspect of the eminence; the mandible is guided caudally, then posteriorly and superiorly back into the temporal fossae (Fig. 68-11). The patient is advised to avoid extreme opening of the mandible such as occurs during laughing and yawning, to begin a soft diet for 1 week, and to apply warm compresses in the TMJ area. NSAIDs and muscle relaxants may be helpful. Patients with chronic dislocation may be helped initially with the application of a Barton bandage (elastic fabricated bandage that wraps around the top of the head and mandible). Intermaxillary fixation with wire and elastics may be necessary. Patients who have difficulty reducing themselves or who are plagued by recurrences may require surgical revision of the eminence for relief.\textsuperscript{1}

**Hemorrhage**

Oral hemorrhage is a common complication of dental scalings, periodontal surgery, and dental extractions. Hemorrhage is controlled easily with local measures postoperatively. Patients may have sustained or recurrent hemorrhage after these procedures, however, and present to the ED. History should be obtained for recent dental procedures, drugs with antiplatelet activity such as aspirin, underlying coagulopathy, or a history of spontaneous bleeding. Spontaneous gingival hemorrhage without an inciting factor warrants a screen for coagulopathy and a complete blood count and differential. Diseases that result in spontaneous gingival hemorrhage are discussed in the section on oral manifestations of systemic disease. Management of coagulopathies caused by factor deficiencies requires factor replacement and administration of aminocaproic acid if there has been a recent dental extraction or periodontal surgery.\textsuperscript{1}

Bleeding after extraction is the most common cause for oral hemorrhage. History of cigarette smoking, excessive spitting, or using straws is helpful information because each behavior

---

**Figure 68-11.** Reduction of temporomandibular joint dislocation. The temporomandibular joint is illustrated in normal and dislocated positions. **A,** Closed position, with the mandibular condyle resting in the mandibular fossa behind the articular eminence. **B,** In maximally open position, the mandibular condyle is just under and slightly behind the articular eminence. **C,** In dislocated position, the mandibular condyle moves forward and upward slightly above the articular eminence; muscle spasm then occurs. **D,** To reduce dislocation, the thumbs are placed intraorally and lateral to the lower molars and pressure is applied to the lower molar ridge area near the jaw angle in a downward and backward direction. **E,** When the mandibular condyle has cleared the articular eminence, muscle contraction returns the jaw to a normal closed position. (Redrawn from Rose LF, Hendler BH, Amsterdam JT: Temporomandibular disorders and odontic infections. Consultant 22:125, 1982.)
creates negative pressure in the oral cavity, which dislodges blood clots from the socket. Excessive clots should be removed from the oral cavity. The patient should be allowed to bite on gauze for 20 minutes. If bleeding has not stopped, the extraction site should be infiltrated with 2% lidocaine with 1:100,000 epinephrine so that the tissue blanches. Gauze pressure should be repeated for another 20 minutes. If bleeding continues, the socket should be packed with an absorbable gelatin sponge or oxidized regenerated cellulose and secured with a No. 4-0 silk suture. Gauze pressure is applied again. Failure to respond to these measures warrants an evaluation for an underlying coagulopathy. Patients who have had multiple extractions without adequate bone recontouring and soft tissue closure may require revision of the surgical site to achieve hemostasis.1

Patients who have bleeding after periodontal surgery usually respond to local measures and continued application of gauze pressure. Patients who are bleeding excessively after a deep scaling may be helped by injection of local anesthetic with epinephrine or the placement of a periodontal pack. Patients who recently have undergone periodontal surgery involving gingival flaps may have dislodged the periodontal packs that were placed to ensure proper tissue alignment and wound healing. The periodontist should be informed if possible so that the pack can be replaced as soon as possible to ensure appropriate healing.

---

**KEY CONCEPTS**

- The most common nontraumatic dental emergencies are pain from dental caries, periodontal abscesses, and spread of infection of dental origin.
- The most important concern of dental infection is any compromise of the airway.
- Fractures of teeth are managed differently depending on which structures are involved—enamel, dentin, or pulp exposure.
- Avulsed teeth must be reimplanted as quickly as possible and are best preserved in Hank’s solution.
- Soft tissue injuries, such as lip lacerations, when involved with dental injuries should be managed after the teeth have been stabilized.

Background and Epidemiology

Two percent of emergency department (ED) patients have eye complaints, including primary ophthalmologic pathology, infectious problems, and traumatic injuries. Eye injuries account for 3.5% of all occupational injuries in the United States, and about 2000 U.S. workers injure their eyes each day. The majority of eye complaints can be treated without ophthalmologic consultation, but a few require ophthalmologist involvement as well as immediate action. Some specific problems such as central retinal artery occlusion and caustic exposure require emergent therapy, even as assessment proceeds. Many other ophthalmologic conditions can be evaluated with a history and examination before treatment by the emergency physician.

Figures 69-1 and 69-2 are provided as brief reviews of normal ocular anatomy and funduscopic appearance.

OCULAR TRAUMA

Perspective

A systematic evaluation of the periorbital and orbital structures aids in the evaluation of patients with ocular trauma. Many extraocular structures are found in close proximity, and concomitant, nonocular injury is common. Penetrating and blunt ocular trauma may involve several eye structures.

Nonpenetrating Trauma

Orbit and Lid

Clinical Features and Management

Contusion. Blunt injury to the orbits and surrounding tissues results in ecchymosis, swelling, and an often dramatic appearance. Related significant injury must be considered. Basilar skull fractures may occur with bilateral ecchymosis (raccoon eyes). Underlying globe injury may be present, and complete examination may be impeded by swelling. The emergency physician should attempt to visualize and examine all structures underlying the eyelids and obtain an accurate visual acuity. This should be done soon after the patient presents, before further swelling occurs. Examining the structures underlying severely swollen eyelids is difficult. A Desmarres retractor may help avoid global pressure.

Treatment of isolated soft tissue injury to the eyelids and surrounding area is symptomatic. Head elevation and intermittent cold compresses started in the ED can be continued for 48 hours to decrease the pain and swelling. Complete resolution takes 2 to 3 weeks. Patients should be instructed to seek follow-up care for any increase in pain or swelling, decreased vision, double vision, or significant flashing lights or “floaters.”

Orbital Wall Fractures. When blunt force causes an acute rise in intraorbital pressure, the thin walls of the orbit frequently fracture. Prolapse of orbital soft tissues into the maxillary sinus may result because the orbital floor is generally the weakest point. Entrapment of the inferior rectus and inferior oblique ocular muscles, orbital fat, and connective tissues results in enophthalmos, ptosis, diplopia, anesthesia of the ipsilateral cheek and upper lip, and limitation of upward gaze. Subcutaneous orbital emphysema may be palpable. Associated globe injuries occur in 10 to 25% of patients with orbital floor fractures. Radiographic examination of the face can help but is imperfect. A computed tomography (CT) scan of the orbits with axial and coronal views is preferred (Fig. 69-3). Plain x-ray films have limited utility given the lower sensitivity to delineate soft tissue structures and extent of bony deformity. On x-ray film, the teardrop sign, a bulge extending from the orbit into the maxillary sinus, and an air-fluid level in the maxillary sinus are indirect signs of orbital floor injury. If the fracture involves an infected sinus, treatment consists of nasal decongestants, broad-spectrum oral antibiotics, and ice packs to the orbit for 48 hours. Some ophthalmologists use steroids to reduce swelling. Surgical repair is only for persistent diplopia or cosmetic concerns and is generally not performed until swelling subsides in 7 to 10 days. Patients can usually be discharged to be reevaluated by an ophthalmologist in 1 to 2 weeks.

Medial orbital wall fractures, through the lamina papyracea of the ethmoid bone, involve entry into the ethmoid sinus. Clinical features include orbital emphysema and epistaxis. Diplopia from medial rectus impingement can occur. The finding of orbital emphysema should prompt a search for associated injury. Rarely is orbital emphysema significant enough to compress the optic nerve and result in acute visual loss. In most cases, orbital emphysema is a benign finding that resolves with time. Prophylactic antibiotics are not needed unless the fracture involves an infected sinus. Patients with orbital floor and medial orbital wall fractures should avoid blowing their noses and performing Valsalva maneuver to limit the extent of emphysema.
Orbital rim fractures are also common. They are a result of direct force.

Retrobulbar Hemorrhage. Orbital hemorrhage in the potential space surrounding the globe may occur after blunt trauma and injury to the orbital vessels. Significant hemorrhage results in an acute rise in intraorbital pressure that is transmitted to the globe and optic nerve. This may result in occlusion of the central retinal artery. Clinical findings include proptosis, limitation of ocular movement, visual loss, and increased intraocular pressure. An orbital CT scan demonstrates a hematoma.

When a retrobulbar hematoma compromises retinal circulation, immediate ophthalmologic consultation for decompression is warranted. Treatment of increased intraocular pressure includes carbonic anhydrase inhibitor, topical beta-blocker, and intravenous (IV) mannitol. A lateral canthotomy can be done in the ED as a temporizing measure before definitive decompression.3

Cornea and Conjunctiva

Clinical Features and Management

Chemical Burns. Exposure of the eye to chemicals is a true ocular emergency. Exposure to strong alkaline chemicals, found in drain cleaners, chemical detergents, industrial solvents, and as lime in plaster and concrete, produces a liquefactive necrosis that penetrates and dissolves tissues until the alkaline agent is removed. Acid burns tend to be less devastating than alkali burns because acidic exposure causes coagulation necrosis and the precipitation of tissue proteins limits the depth of the injury.

Treatment should begin at the scene with immediate irrigation using copious amounts of water. Irrigation should continue for at least 30 minutes before any attempt to transport the patient to the hospital. Any particles should be removed from the fornices using a cotton swab.

Upon hospital arrival, irrigation should continue. Use of irrigation devices, such as a Morgan® Lens (Mortan Inc., Missoula, Mont), can assist in delivering continuous irrigation to the affected eye. Topical anesthetics and manual lid retraction may be needed for proper irrigation. Irrigation is needed until the pH of the tear film is neutral as tested by Nitrazine paper dipped into the inferior conjunctival fornix. If the pH tested immediately after irrigation is still alkaline, irrigation should be reinstituted. A normal pH should be checked again 10 minutes after the cessation of irrigation and periodically thereafter. Treatment after irrigation consists of a cycloplegic (avoid phenylephrine), topical antibiotics, treatment of increased intraocular pressure, and pain management.

Ophthalmologic consultation is indicated in all significant chemical exposures. Identification of the substance and its pH value is important. Alkaline substances with a pH less than 12 and acidic substances with a pH greater than 2 are thought not to cause significant injury, although high concentration and prolonged contact time can alter this general rule and may cause injury.11,12
Severity can be judged by the degree of corneal cloudiness and scleral whitening (Fig. 69-4). Long-term complications include perforation, scarring, and neovascularization of the cornea; adhesions of the lids to the globe (symblepharon); glaucoma; cataracts; and retinal damage.

**Miscellaneous Irritants, Solvents, Detergents, and Glues.** Unknown exposures should initially be treated as though they were an alkali or acid exposure, prompting immediate irrigation. Detergents generally cause conjunctival irritation only. More irritating substances may denude the corneal epithelium and cause anterior chamber inflammation. After copious irrigation, these injuries should be treated as corneal abrasions.

Aerosol exposures are common. Intraocular foreign bodies may result from the propellant. Exposure to the compounds found in personal defense devices (e.g., Mace) should be treated in the same manner as other chemical injuries.

Super glue (cyanoacrylate adhesive) exposure is also common. These glues harden rapidly, and typically the eyelids are sealed shut. Misdirected lashes and the hardened super glue may act as a foreign body and cause corneal defects. Gentle traction on the eyelids and separating glued eyelashes may open the eyelids. If the eyelids are sealed shut in a normal anatomic position and cannot be opened with gentle traction, the eye may be left alone, allowing time for the super glue to dissolve by physiologic mechanisms over several days. If the eyelids are inverted and sealed shut, surgical intervention may be needed. Attempts to dissolve the super glue with other substances should be avoided. Ophthalmic consultation should be obtained for super glue exposures.

**Thermal Burns.** Thermal burns affect the eyelids more than the globe because of reflex blinking and Bell’s phenomenon.Superficial eyelid burns can be treated by irrigation and topical antibiotic ophthalmic ointment. Second- or third-degree eyelid burns need ophthalmic consultation. Hot liquid splashes and cigarette ashes to the cornea usually result in a superficial corneal epithelial injury and are treated as corneal abrasions. Molten metals and other hot objects may result in globe perforation.

**Radiation Burns (Ultraviolet Keratitis).** Ultraviolet light from sun lamps, tanning booths, high-altitude environments, snow or water reflection, or a welder’s arc results in direct corneal epithelial damage. After a latent period of 6 to 10 hours, patients develop a foreign body sensation, tearing, intense pain, photophobia, and blepharospasm. Topical opthalmic anesthetics facilitate physical examination. Examination reveals decreased visual acuity, injected conjunctiva, and diffuse punctate corneal lesions, often with a discrete lower border defining the cornea protected by the inferior lid. Treatment consists of a short-acting cycloplegic and a topical broad-spectrum antibiotic ointment, although evidence for the latter is scant. Oral opioids are commonly needed. Patients should not be prescribed topical anesthetics because frequent use retards healing and can lead to corneal ulcer formation. Patients should be counseled on the adverse effects of ultraviolet radiation and should be educated on using various protective devices. Patients should have ophthalmologic or ED follow-up in 24 hours if their symptoms are not resolved.

**Mechanical Corneal Abrasions.** Patients complain of a foreign body sensation, pain, photophobia, and decrease in visual acuity. The degree of relief afforded by topical anesthetics can differentiate corneal injury from other causes of acute eye pain. Physical examination reveals injected conjunctiva, decreased visual acuity if the defect is large or lies in the visual axis, and demonstration of the epithelial defect with slit-lamp examination using fluorescein (Fig. 69-5). Aqueous humor leaking from the anterior chamber during fluorescein examination suggests a corneal perforation (Seidel’s test). Foreign bodies of the lid conjunctiva must be identified. Treatment consists of cycloplegia and topical antibiotics. Recent data also suggest that treatment with topical nonsteroidal anti-inflammatory medications reduces the pain patients experience with corneal abrasions. Patients with contact lenses should be treated with topical antibiotics with antipseudomonal coverage. Eye patching should be avoided, especially in injury involving vegetable matter or contact lens use. Data suggest that eye patching confers no benefit in healing small, uncomplicated corneal abrasions. Patients with corneal abrasions should not wear their contact lenses. Oral pain medications may be needed. There are no known cases of clinical tetanus developing from a simple corneal abrasion. Given the lack of evidence, simple corneal abrasions should not require tetanus immunization. However, tetanus immunization should be considered in any tetanus-prone injury such as corneal perforation or injuries containing dirt and organic matter. Patients should not be prescribed topical anesthetic agents as these may lead to corneal ulcer and bacterial infection. Patients should have ophthalmologic or ED follow-up in 24 hours if their symptoms have not resolved.

**Corneal Foreign Bodies.** Patients with corneal foreign bodies experience pain, foreign body sensation, injected conjunctiva, tearing, and blepharospasm. Administration of a topical ophthalmic anesthetic facilitates physical examination. Diagnosis
is made with slit-lamp examination (Fig. 69-6). After a topical anesthetic is applied, the initial attempt at removing corneal foreign bodies should be with a stream of sterile saline solution. If this fails, the foreign body should be removed using a commercial eye spud or 25-gauge needle with a 1- to 3-mL syringe as a handle and magnification, generally the slit lamp. The patient must be totally cooperative and the patient’s head firmly stabilized within the slit lamp. Alternatively, a short plastic 20-gauge catheter can be placed on a syringe and, with slit-lamp visualization, the foreign body can sometimes be irrigated out of the cornea.

Iron-containing corneal foreign bodies leave a residual rust ring (Fig. 69-7). Removal of the rust ring should be left to the ophthalmologist or a return visit to the ED for 24-hour follow-up because the affected cornea gradually softens, and the rust migrates toward the corneal surface, making removal easier.

Ophthalmologic consultation for corneal foreign bodies is recommended if a large area of the visual axis is involved, the object is deeply embedded within the cornea, the risk of perforation is increased for any reason, or there are multiple foreign bodies.

Treatment after foreign body removal is similar to that for corneal abrasion, with ophthalmologic or ED follow-up within 24 hours for patients who require rust ring removal or who remain symptomatic.

Use of high-speed drills, saws, grinders, and pounding objects or involvement in explosions should alert the emergency physician to the likelihood of an intraocular foreign body with perforation. CT can be used to rule out the diagnosis of an intraocular foreign body.

Conjunctival Foreign Body. Conjunctival foreign bodies can be removed under topical anesthesia with a cotton-tipped applicator or fine forceps. Topical phenylephrine can be used to reduce the conjunctival bleeding.

Subconjunctival Hemorrhage. Rupture of small subconjunctival blood vessels is common and occurs as a result of trauma or Valsalva maneuver or without apparent cause. Patients complain of its appearance. Pain, diminished visual acuity, or photophobia suggests a more serious pathologic condition. Subconjunctival hemorrhage is flat, bright red, smooth, limited to the bulbar conjunctiva, and sharply demarcated at the limbus (Fig. 69-8). Subconjunctival hemorrhage must be distinguished from bloody chemosis, which is indicative of more serious globe pathology. Bilateral or recurrent subconjunctival hemorrhage may require workup for bleeding diathesis.

Treatment consists of local cold compresses for 24 hours, with resolution in 2 to 3 weeks.

Anterior Chamber and Iris

Clinical Features and Management

Traumatic Hyphema. Disruption of blood vessels in the iris or ciliary body results in hyphema, blood in the clear aqueous humor in the anterior chamber. If the patient is sitting, the blood often layers and forms a meniscus with the aqueous humor. Hyphemas range from minimal blood seen only with the slit lamp to the “eight ball” or total hyphema with blood that has clotted. Patients complain of pain, photophobia, and decreased visual acuity. The emergency physician sees the blood directly or with the aid of the slit lamp (Fig. 69-9). There is generally no afferent pupillary defect (or Marcus-Gunn pupil) present. An afferent pupillary defect occurs when the abnormal eye paradoxically dilates rather than constricts when light is directed to that eye. Intraocular pressure may also rise.

Management of hyphema must be individualized for a given patient. Selected low-grade hyphemas in reliable patients may be managed on an outpatient basis; all other patients should be admitted. General therapy includes elevating the bed 30 to
Figure 69-9. Small hyphema layering out in the inferior portion of the anterior chamber.

Figure 69-10. Ciliary flush. Note that conjunctival injection is most prominent immediately around the limbus.

45 degrees, bed rest, and limiting eye movement such as reading. The affected eye should also be protected with a patch and shield. Analgesics are appropriate, but the patient should avoid taking aspirin and other platelet inhibitors. Antiemetics and sedatives should be used cautiously. Increased intraocular pressure occurs as a result of aqueous flow blockage from the blood present. In patients without sickle cell disease, initial treatment is a topical beta-blocker; a topical alpha-agonist or topical carbonic anhydrase inhibitor is added if needed. Oral acetazolamide or IV mannitol may also be used.

Specific treatment for hyphema with miotics, mydriatics, cycloplegics, steroids, and antifibrinolytics such as aminocaproic acid varies depending on the specific clinical situation and is best left to the ophthalmologist. Failure of medical therapy to control high intraocular pressure, failure of a large clot to resolve, and corneal blood staining are indications for surgical intervention. There are case reports on the use of anterior chamber thrombolytics in those whose large clot fails to resolve.

The major complication of hyphema is rebleeding, which occurs after 2 to 5 days when the initial clot retracts and loosens. Rebleeding is more common in those with visual acuities of 20/200, initial hyphema covering more than one third of the anterior chamber, medical attention delayed more than 1 day after injury, and elevated intraocular pressure at the initial examination. Other complications include corneal blood staining, acute or chronic glaucoma, and anterior or posterior synchia formation.

Patients with hemoglobinopathies (e.g., sickle cell disease, thalassemia) are at increased risk for hyphema complications. Red blood cells in the anterior chamber sickle in the relatively acidic and hypoxic environment, which leads to decreased aqueous humor outflow and a rapid rise in intraocular pressure. Increased intraocular pressure in a sickle cell patient with a hyphema should be treated with topical beta-blockers. All other anti-glaucoma medications should be prescribed by an ophthalmologist. If needed, methazolamide by mouth, and not acetazolamide, may be used.

Traumatic Iridocyclitis. Blunt injury of the globe may contuse and inflame the iris and ciliary body, resulting in ciliary spasm. Patients complain of photophobia and deep, aching eye pain. Examination reveals perilimbal conjunctival injection (ciliary flush), cells (white or red blood cells) and flare (protein content) in the anterior chamber, and a small, poorly dilating pupil (Fig. 69-10). These symptoms indicate white blood cells and protein as a result of the inflammation. Patients may also experience direct photophobia, when the light is directed to the affected eye, and consensual photophobia when light is directed in the uninvolved eye.

Treatment consists of paralyzing the iris and ciliary body with a long-acting cycloplegic agent, such as homatropine hydrobromide 5%, given four times daily for 7 to 10 days. Prednisolone acetate 1% may be given to help relieve the inflammation if there is no improvement after 5 to 7 days but should be avoided in patients with a corneal epithelial defect. Resolution occurs within 1 week.

Traumatic Mydriasis and Miosis. Blunt injury may result in either pupillary dilatation or constriction and may persist for days. For significant head trauma and altered mental status, a cranial nerve palsy must be ruled out before ascribing pupillary mydriasis to local contusion.

Permanent pupillary mydriasis may result from small radial tears in the pupillary sphincter muscle. The pupil margin may look irregular or scalloped. No specific ED treatment is warranted.

Iridodialysis. Traumatic iridodialysis is a tearing of the iris root from the ciliary body, leading to the formation of a “secondary pupil.” This injury is often the cause of a hyphema. If no associated hyphema is present, no specific ED treatment is needed. Large tears can lead to monocular diplopia and may require surgical correction. Immediate ophthalmologic consultation is warranted when iridodialysis has caused a hyphema or a decrease in visual acuity.

Anterior Chamber Angle Recession. Blunt injury to the ciliary body may cause posterior displacement of the iris and surrounding tissues, deepening the anterior chamber, widening the anterior chamber angle, and causing potential damage to the trabecular meshwork that drains the aqueous humor. Severe damage can cause acute glaucoma.

Scleral and Lens Injuries

Clinical Features and Management

Cataract. If the lens capsule is disrupted by either blunt or penetrating trauma, the relatively dehydrated stroma absorbs fluid, swells, and becomes cloudy. Acute glaucoma may develop from blockage of the aqueous humor flow through the pupil, necessitating surgical intervention. In less severe injury, cataract formation may occur over weeks to months.

Lens Subluxation and Dislocation. Complete disruption of the lens zonule fibers by blunt trauma may result in anterior or posterior dislocation of the lens. Incomplete disruption of the lens zonule fibers results in subluxation of the lens. Lens dislocation may occur with minor trauma in patients with Marfan’s syndrome, homocystinuria, tertiary syphilis, and
other predisposing conditions. Patients complain of monocular diplopia or visual distortion with subluxation and marked visual blurring with dislocation. Examination reveals decreased visual acuity. The edge of a subluxated lens can be seen when the pupil is dilated. Iridodonesis is a trembling or shimmering of the iris after rapid eye movements and is a helpful sign of lens dislocation. Treatment ranges from observation to surgical removal and is dictated by the location of the dislocated lens and associated eye injury. Immediate ophthalmologic consult...

Scleral (Globe) Rupture. Blunt trauma causes scleral rupture by suddenly elevating intraocular pressure. Ruptures are most common at the insertions of the intraocular muscles or at the limbus, where the sclera is thinnest. The diagnosis of scleral rupture is obvious when intraocular contents are visualized; however, occult global rupture can be difficult to diagnose. Patients complain of eye pain and decreased vision. Examination may reveal a bloody chemosis or severe subconjunctival hemorrhage overlying the scleral rupture site. When the rupture occurs at the limbus, an irregularly shaped (teardrop) pupil may also be seen. Uveal prolapse through the scleral wound, appearing as a brownish black discoloration, can also be seen (Fig. 69-11). Although a lower than normal intraocular pressure is a good indication of rupture, tonometry should not be performed in suspected globe rupture. Any maneuvers that increase intraocular pressure need to be avoided. A CT scan, ultrasonography, and indirect ophthalmoscopy all play a role in the diagnosis of occult globe rupture but may be left to the ophthalmologist.

Ophthalmologic consultation is warranted in all cases of suspected or proven globe rupture. Treatment in the ED for a known globe rupture includes avoidance of further examination or manipulation and the placement of a protective metal eye shield to prevent accidental pressure on the globe. The patient should be kept with nothing by mouth and a tetanus injection given as needed. Antiemetics should be given if the patient is nauseated. Broad-spectrum IV antibiotics should be instituted.

Theoretical classical teaching states that the use of succinylcholine is contraindicated in the presence of a penetrating ocular injury because of the rise in intraocular pressure and potential for ocular extrusion, but a search of the literature does not identify a single report of this occurring. One study reported on the use of succinylcholine after pretreatment with nondepolarizing agents in 100 patients with penetrating eye injury; no adverse events were found. Given the need for rapid airway management in a patient with penetrating ocular injury, rapid sequence intubation with succinylcholine and an induction agent is appropriate. Succinylcholine may be preceded by pretreatment with a defasciculating dose of a nondepolarizing neuromuscular blocking agent (e.g., 0.01 mg/kg of vecuronium or pancuronium), but there is no evidence that this definitely improves outcome.

Ophthalmologic consultation is required for all patients with suspected or proven globe rupture.

Posterior Segment Injuries

Clinical Features and Management

Vitreous Hemorrhage. Bleeding into the vitreous may occur from injuries to the retina and uveal tract and their associated vascular structures. Patients complain of decreased visual acuity and floaters. Floaters, described by the patient as dark dots or strands moving in the visual field in the direction of the preceding eye movement, are caused by vitreous blood. There is a diminished red reflex and an inability to visualize the fundus clearly with the direct ophthalmoscope. With vitreous hemorrhage caused by blunt trauma, B-scan ultrasonography is used to search for retinal injury and determine the need for operative repair.

Treatment of vitreous hemorrhage includes elevating the head of the bed to allow settling of the blood and avoiding platelet-inhibiting drugs and Valsalva maneuver. Vitrectomy is performed for vitreous hemorrhage with an associated retinal detachment. Ophthalmologic consultation is warranted for acute traumatic vitreous hemorrhage.

Retinal Injuries. Blunt injury to the retina may result in hemorrhage, a tear or detachment, or commotio retinae. Hemorrhage can occur in the preretinal (subhyaloid), superficial retinal, or deep (subretinal) spaces. Preretinal hemorrhage appears as boat shaped, superficial retinal hemorrhage as flame shaped, and deep retinal hemorrhage as rounded and grape-purple in color.

Tears and detachments from blunt trauma are common. Symptoms include floaters from bleeding, flashing lights from stimulation of retinal neurons, and visual field cuts or decreased visual acuity. Retinal tears or detachments do not cause pain. Examination may reveal the hazy gray membrane of the retina billowing forward (Fig. 69-12), but many tears are peripherally located and not seen with direct ophthalmoscopy. Visual acuity may be normal unless the macula is involved. Indirect ophthalmoscopy is warranted if historical clues to the presence of retinal tears are present. Ophthalmologic consultation is warranted in all cases of suspected or proven retinal detachment. Treatment includes photocoagulation or operative repair; prognosis depends on the condition of the macula.

Commotio retinae occurs after recent ocular trauma. Patients may have decreased visual acuity or be asymptomatic. Examination reveals a cloudy whitening of the involved area that...
subsides in a few weeks with no specific treatment. Serial follow-up is necessary to ensure that retinal tear or detachment has not occurred.

**Optic Nerve Injury.** Significant blunt force to the orbital contents may avulse, transect, compress, or contuse the optic nerve. Fractures may extend into the orbital canal and cause optic nerve damage. Patients complain of visual field cuts or decreased visual acuity. Examination reveals an afferent pupillary defect, assorted visual field cuts, a decrease in visual acuity, or total blindness. The optic disk is normal initially, but pallor eventually develops. An orbital CT scan can help define the location and extent of injury. Management of traumatic optic neuropathy is controversial. High-dose methylprednisolone and surgical decompression have been used with varying degrees of success. When edema or bleeding within the optic nerve is visualized, or with significant reduction in visual acuity, high-dose steroids can be used. Surgical decompression should be considered when decreasing visual acuity is occurring from a known orbital canal fracture.

**Penetrating Trauma**

**Lacerations of the Eyelids**

**Clinical Features and Management.** Any laceration involving the eyelids should prompt a search for penetrating globe injury and, if indicated, a thorough search for a foreign body. Soft eye pads should be avoided to prevent increases in intraocular pressure.

Emergency physicians can manage simple horizontal or oblique partial-thickness lid lacerations. These can be closed primarily using 6-0 or 7-0 nylon interrupted sutures. Sutures should be removed in 3 to 5 days.

Several lid lacerations have a high likelihood of cosmetic or functional complications and should be managed by ophthalmologists or plastic surgeons skilled in this area. The following lid lacerations fall into the category of complex lid lacerations and need immediate referral.

1. Lacerations involving the lid margins.
2. Lacerations involving the canalicular system. Injury to the canalicular system should be suspected in any laceration involving the medial lower eyelid area (Fig. 69-13).
3. Lacerations involving the levator or canthal tendons.
4. Laceration through the orbital septum. Orbital fat protrudes through septal lacerations into the wound. Because eyelids have no subcutaneous fat, the appearance of fat in a lid laceration confirms this diagnosis. These wounds are associated with a high incidence of globe penetration and intraorbital foreign bodies.
5. Lacerations with tissue loss.

**Conjunctival Lacerations**

**Clinical Features and Management.** Lacerations of the bulbar conjunctiva commonly involve intraocular foreign bodies or underlying scleral perforation. Slit-lamp examination can distinguish superficial from deeper lacerations. Small, superficial lacerations require no suturing and heal quickly. Topical prophylactic ophthalmic antibiotics are advisable. Larger (>1 cm) and deeper lacerations may require repair by an ophthalmologist.

**Corneal and Scleral Lacerations**

**Clinical Features and Management**
